Figure 2 A scoring expression database for three items with primary answer keys (PAK) and auxiliary-scoring expressions (ASE)

to be generated from the examinees' responses and reviewed by subject matter experts.

Figure 2 presents an elaborated scoring expression database table that incorporates the auxiliary-scoring expressions for the three items shown in Figure 1. A new database field has been added called 'Status', where PAK refers to the primary answer key and ASE denotes a auxiliary-scoring expression. The point values of the ASE records are set to zero. If any of those auxiliary-scoring expressions were subsequently judged to provide valid information, the database field could easily be set to a nonzero point value and the batch of response records rescored. This approach can incorporate fractional or even negative scoring weights.

Using this framework, item analysis becomes a set of prescribed statistical procedures for operating on stored scoring expression records. This simple database structure easily accommodates a wide variety of scoring expressions and scoring evaluators, making it relatively straightforward to generalize a common set of item analysis methods to a wide variety of item types. For example, some of the same techniques used for multiple-choice items can easily be adapted for use with complex, computer-based performance exercises.

Statistical Analysis Methods for Evaluating Scoring Expressions

There are many types of statistical analyses we might employ in an item analysis. This section highlights some of the more common ones, including tabular and graphical methods of presenting the item analysis results.

As noted earlier, traditional item analysis methods have primarily been devised for MC items. These include descriptive statistics such as frequency distributions, means, variances, tabular, and graphical presentations of score-group performance, and various discrimination indices that denote the degree to which an item or scoring expression differentiates between examinees at various levels of apparent proficiency. This section highlights four broad classes of item analysis statistics: (a) unconditional descriptive statistics; (b) conditional descriptive statistics; (c) discrimination indices; and (d) IRT misfit statistics and nonconvergence.

Unconditional Descriptive Statistics

Perhaps the most obvious descriptive statistics to use in an item are the count or percentage of total examinees that hit on a particular scoring expression, the mean score, and the variance. The count or percentage of hits on a scoring expression can highlight problems such as scoring expressions that no one ever chooses. The mean provides an indication of difficulty and the variance indicates whether the full range of possible scores is being adequately used.

Means and variances can also be computed conditionally, as discussed in the next section. The point values can also be aggregated over multiple scoring expressions that belong to the same unit (e.g., an SR item with multiple correct answers as unique scoring expressions). Provided that an appropriate database field exists for grouping together multiple scoring expressions (e.g., an item identifier), it is relatively straightforward to add this aggregation functionality to the item analysis system.

Conditional Descriptive Statistics

The capability of scoring expressions to distinguish between individuals at different levels of proficiency is referred to as *discrimination*. Scoring expressions that discriminate well between the examinees at different proficiency levels are usually considered to be better than expressions that fail to differentiate between the examinees. Discrimination can be evaluated by computing and reporting descriptive statistics conditionally for two or more score groups, $k = 1, \dots, G$, usually based on total test performance or some other criterion score. Conditional descriptive statistics include frequencies, means, and standard deviations that are computed and reported in tabular or graphical form for each score group.

The criterion test score is essential for creating the score groups used in computing the conditional statistics. The raw total test score is usually used as the criterion score for paper-and-pencil tests. Even then, the total test score, $T_j = \sum y_{ij}$, must be systematically adjusted by subtracting y_{ij} for each examinee, $j = 1, \dots, N$. The raw total test score also fails as the optimal choice as the criterion test score when adaptive testing algorithms are used, or when the test forms seen by individual examinees may differ in average difficulty. For example, a very able

examinee and a less-able examinee can have the same raw score on an adaptive test simply because the more able examinee was administered more difficult items.

A useful alternative to the total test score is an IRT (*see Item Response Theory (IRT) Models for Dichotomous Data*) ability score⁴ computed from operational test items, using a set of stable item parameter estimates from an item bank. Assuming that all of the IRT item parameters in the item bank have been calibrated to a common metric, the estimated criterion score, T_j , $j = 1, \dots, N$, will be on a common scale, regardless of which test form a particular examinee took. T_j can then be computed once for each examinee and then used in a simultaneous item analysis of all scoring expressions.

Given the criterion scores obtained for all examinees in the item analysis sample, two or more score groups can be formed, $k = 1, \dots, G$. Item analyses typically form the score groups to have approximately equal numbers of examinees in each group – that is, $F_1 = F_2 = \dots = F_G$ – versus using equally spaced intervals on the score scale.

One of the most common conditional item analysis methods is a high–low table of conditional frequencies or relative frequency percentages. This type of table provides a convenient way to simultaneously evaluate the correct answers and incorrect options (distractors) for MC items. The same technique can easily be extended to other types of SR and CR item. First, two contrasting score groups are formed, based on the criterion test scores. Kelley [11] recommended that the two score groups be formed by taking the upper and lower 27% of the examinees as the high and low groups – optionally, other percentages, up to a 50:50 split of the sample, have been effectively used.

Figure 3 shows a distractor analysis for a single MC item with five response options. The correct

answer is ‘B’ (i.e., the scoring evaluator returns $y_i = 1$ if $r_i = \text{‘B’}$). The remaining four response options are auxiliary-scoring expressions. The distractor analysis indicates that 91% of the examinees in the high score group selected the correct response. In contrast, only 26% of the low-score group examinees selected the correct answer. All of the other response options were attractive to the examinees in the lower score group.

A multi-line plot can also be used to simultaneously evaluate a number of scoring expressions when more than two score groups are used. For example, suppose that we compute criterion scores and categorize the examinees into five equal-sized groups or quintiles (i.e., 0–20% of the examinees are placed in Group 1, 21–40% in Group 2, etc.). The multi-line plot shows the proportion of examinees within each group who selected each of the scoring expressions. Figure 4 shows the simultaneous percentages of examinees within five equal-sized score groups, labeled 1 to 5 along the horizontal axis. There is one line for each of the six scoring expressions for ITM002, shown earlier in Figure 2. Scoring expression EXPR000005 is the primary answer key. The remaining expressions are auxiliary scoring expressions. The multi-line plot shows that the majority of the candidates in score groups 4 and 5 properly selected both options ‘A’ and ‘E’. The remaining lines are fairly flat. This type of plot provides two types of useful information for evaluating the scoring expressions. First, if the line for a primary answer key is decreasing across the low-to-high score groups, there may be a serious problem with that particular key. Second, if any auxiliary-scoring expression demonstrates an increasing trend across the low-to-high score groups, that expression might be a valid secondary answer key (or the correct key, if line for the primary answer

Response options	A	B*	C	D	E	Omits total
High score group (N_H)	6	179	7	5	0	0 197
Low score group (N_L)	54	52	37	47	5	2 197
Total group (N)	105	448	75	83	27	3 741
High score group %	3%	91%	4%	3%	0%	0% 100%
Low score group %	27%	26%	19%	24%	3%	1% 100%
Total group %	14%	60%	10%	11%	4%	0% 100%

Figure 5 A summary of conditional descriptive statistics for the criterion test for five scoring expressions associated with an MC item

key is simultaneously decreasing across the score groups).

A third way to indicate how well the scoring expressions discriminate is to compute the means and standard deviations of the criterion test values conditional for examinees who ‘hit’ on each of the scoring expressions. Examinees whose responses match the primary answer keys should have higher mean scores than those whose responses match the auxiliary answer keys. This method is particularly useful with computer-adaptive tests if IRT scoring is used to compute the criterion scores.

Figure 5 presents a table of conditional descriptive statistics for the criterion scores associated with the five expressions for ITM001 shown earlier in Figure 2. The criterion scores reported are IRT proficiency scores computed for each examinee. Therefore, all of the proficiency scores are on the same scale. As we might hope, the mean score on the criterion test is higher for the primary answer key than for any of the other options. Similar to the distractor analysis, the implication is that higher scoring examinees tend to select the correct response more frequently than lower scoring examinees.

Figure 6 presents the same information as Figure 5, but in graphical form. The symbols distinguish between the primary answer key (PAK) and the auxiliary-scoring expressions (ASI). The error bars denote the standard deviations of the proficiency scores about the mean proficiency score for each expression. If the PAK were incorrect, the mean might be lower than some or all of the ASE means. A possible valid auxiliary-scoring expression would appear with a higher mean than the other ASE values. If the PAK versus ASE means are similar in magnitude, or if the standard error bars overlap a great deal, we might look to change one or more scoring expressions to extract more discriminating information.

Discrimination Indices

There are three discrimination indexes typically used in an item analysis: the U-L index, the point-biserial correlation, and the biserial correlation. These tend to augment some of the descriptive conditional statistical methods.

The U-L index of discrimination, sometimes called *D*, (see references [7] and [11]) is the simple difference between the mean scores for the examinees

Figure 6 Plot of conditional means and standard deviations for the criterion test for five scoring expressions associated with an MC item

in the upper (U) 27% and the lower 27% of the distribution of total test scores. That is,

$$D = \frac{\bar{Y}_{Ui} - \bar{Y}_{Li}}{m_i} \quad (5)$$

where m_i denotes the total possible points for the item. When applied to dichotomous items, D is the simple difference between the P values (item means). The upper bound of D is +1.0; the lower bound is -1.0. $D \geq 0.4$ is generally considered to be satisfactorily. Values in the range $0.2 \leq D \leq 0.39$ indicate possible problems, but nothing serious. Values of $D \leq 0.19$ are considered to be unacceptable and indicate a scoring expression that should be eliminated or that requires serious revision.

Point-biserial and biserial correlations can be used to denote the relative strength of the association between getting a 'hit' on a particular scoring expression and the criterion test score. When the expression-criterion score is positive and reasonably high, it indicates that higher performance on the total test is associated with correspondingly higher performance on the item or scoring expression. Low values

indicate nondiscriminating items and negative values usually signal a potential serious flaw in the scoring expression. When scoring expression represents a dichotomously score, we use a point-biserial correlation.

A **point-biserial correlation** is the **Pearson product-moment correlation** between a dichotomous and a continuous variable,

$$r_{pbis(i)} = \frac{\bar{T}_{i+} - \bar{T}}{s_T} \sqrt{\frac{p_i}{(1 - p_i)}} \quad (6)$$

where $\bar{T}_{i+}$ is the mean criterion test score for examinees who correctly answered item i , $\bar{T}$ is the mean for the entire sample, s_T is the sample standard deviation, and p_i is the item P value.

If we assume that there is an underlying normal distribution of ability that is artificially dichotomized for the primary answer key score, as well as for hits on the auxiliary-scoring expressions, we can use a biserial correlation. The biserial correlation is computed as

$$r_{bis(i)} = \frac{\bar{T}_{i+} - \bar{T}}{s_T} \sqrt{\frac{p_i}{h}} \quad (7)$$

where $\bar{T}_{i+}$, $\bar{T}$, s_T , and p_i are defined the same as for the point-biserial correlation. The variable h represents the ordinate of the standard normal curve at a z -value corresponding to p_i .

The point-biserial is easier to compute than the biserial correlation, but that is no longer a major consideration for computerized item analysis. However, the biserial correlation is about one-fifth greater in magnitude in the mid-range of P values. The relationship between r_{pbis} and r_{bis} is

$$r_{bis(i)} = r_{pbis(i)} \frac{\sqrt{p_i q_i}}{h}. \quad (8)$$

Some test developers prefer the biserial as an overall discrimination indicator – perhaps because it is systematically higher than the point biserial. However, the point-biserial correlation tends to be more useful in item analysis and test construction.

As part of an item analysis, point-biserial correlations can be presented in much the same way as graphics or tables computed using conditional statistics. Primary answer keys with positive values of the point biserial – usually at least 0.3 or higher – are considered to be acceptable. Primary answer keys within the range $0.1 \leq r_{pbis} \leq 0.29$ typically warrant serious scrutiny, but may still be associated with a useful item. The utility of keeping primary answer keys where $r_{pbis} \leq 0.1$ is highly questionable.

If each hit on a secondary scoring expression is treated as a dichotomous score (i.e., $y_{ij} = 1$, regardless of the point values for the scoring expression) point-biserial correlations can also be computed for the auxiliary-scoring expressions. Plausible secondary answer keys can sometimes be detected by finding ASEs with moderate-to-high r_{pbis} values. If the r_{pbis} value associated with an ASE is higher than the PAK r_{pbis} , the analysis may indicate that the primary answer key is a miskey and simultaneously suggest what the appropriate primary key should be.

IRT Misfit Analysis and Convergence

Item response theory (IRT) can also be used to evaluate the quality of each scoring key (e.g., [9] and [10]). There are two broad classes of analyses that deserve mention here. The first is IRT misfit analysis. IRT misfit analyses can be employed to evaluate how well the empirical response data match a probability function curve produced by a particular IRT

model. Primary answer key scoring expressions that fail to fit a given IRT model may signal serious scaling problems if the item is retained for operational scoring. IRT model misfit can further be evaluated to uncover dependencies among various scoring expressions, to detect differential functioning of the items for different population subgroups, or even to suggest possible multidimensionality problems – especially when a test is assumed to measure one primary trait or a composite of primary traits.

A second type of IRT analysis involves a review of convergence problems with respect to particular item types. Some of these problems may be due to nondiscriminating scoring expression, violations of IRT model assumptions that lead to statistical identifiability problems, or messy data that can be traced to faulty instructions to the examinees or an overly complex user interface used with a new CBT item type.

A thorough discussion of IRT or these issues is far beyond the scope of this entry. Nonetheless, as testing organizations move more toward using IRT – especially with CBT and some of the new item types – it is essential to find ways to discover problems with the scoring expressions, before the items are used operationally. As noted in the previous two sections, item analysis using conditional descriptive statistics or scoring expression-criterion test correlations, where the latter is based on an IRT proficiency score, is also an approach that combines IRT and classical test item analysis methods.

Notes

1. The focus in this entry is on large-scale testing applications. In classroom settings, item analysis can be employed to help teachers evaluate their assessments and to use the results to improve instruction. However, this assumes that the teachers have proper training in interpreting item analysis results and are provided with convenient and easy-to-use software tools [10].
2. Human raters can be considered to be *scoring evaluators* and incorporated into this framework.
3. Introducing obvious dependencies among the scored responses is typically frowned upon as an item writing practice. Nonetheless, it can be argued that the scoring and item analysis system should be capable of handling those types of responses.
4. The three most common estimators used for IRT scoring are a maximum likelihood estimator, a Bayes

mean estimator, or a Bayes mode estimator. Hambleton and Swaminathan [9] provide details about IRT estimation and scoring.

Item Bias Detection: Classical Approaches

In the 1960s, concern was raised on the fairness of educational and psychological tests. The test performance of American minority group members stayed behind the performance of Whites, and tests were blamed for being biased against minorities [2]. Methods were developed to detect biased items, but these methods did not clearly distinguish between impact and item bias. Impact means that between-group item performance differences are explained by between-group ability distribution differences, whereas item bias means that between-group item performance differences exist for examinees of equal ability from different groups [10].

Classical test theory (CTT) applies to the observed test score [11]. The observed test score is used as an estimate of an examinee's true test score. Scheuneman [16] proposed to study item bias conditional on the test score: She considered an item to be biased between different (e.g., ethnic, sex, cultural) groups when item performance differs between examinees from different groups who have the same test score. Her proposal founded CTT-based item bias detection methods that do not confuse item bias and impact.

The classical concept of item bias had a rather limited scope. It applied to achievement and ability tests that consist of dichotomously scored items. The concept was broadened into several directions. The term 'item bias' was replaced by the more neutral term **differential item functioning** (DIF), and DIF was extended from achievement and ability tests to attitude and personality questionnaires, and from dichotomously scored item responses to item response scales that have more than two answer categories.

The situation is considered of a test that predominantly measures one latent variable, such as a cognitive ability, attitude, or personality trait. The test consists of n items; the observed test score, X , is the unweighted or weighted sum of the n item scores. It is studied whether an item is differentially functioning with respect to a violator variable V [14]. Usually, V is an observed group membership variable, where the focal group ($V = f$) is the particular group of interest (e.g., a minority group) and the reference group ($V = r$) is the group with whom the focal

group is compared (e.g., the majority group). An item is differentially functioning between focal and reference group when the item responses of equal ability (trait level) examinees (respondents) differ between the two groups.

Dichotomous Item Responses

The items of the test are dichotomously scored: $I = 1$ for a correct (affirmative) answer and $I = 0$ for an incorrect (negative) answer. $P_{ir}(x)$ and $P_{if}(x)$ are the probabilities of giving the correct (affirmative) answer to the i th item, given the test score, in the reference and focal group, respectively. $P_{ir}(x)$ and $P_{if}(x)$ are the regression functions of the item score on the test score, that is $P_{ir}(x) = E(I_i | X = x, V = r)$ and $P_{if}(x) = E(I_i | X = x, V = f)$. Under CTT, item i is considered to be free of DIF if

$$P_{ir}(x) = P_{if}(x) = P_i(x) \quad \text{for all values } x \text{ of } X. \quad (1)$$

The **Logistic Regression, Logit, and Mantel-Haenszel Methods** for DIF detection use similar specifications of (1). The regression function of the Logistic Regression Method [18] is

$$P_i(x) = \frac{e^{\beta_{i0} + \beta_{i1}x}}{1 + e^{\beta_{i0} + \beta_{i1}x}}, \quad (2)$$

where β_{i0} is the difficulty (attractiveness) parameter and β_{i1} the discrimination parameter of the i th item. Under Model (2), the CTT definition is satisfied if the parameters of the reference and focal group are equal, that is, $\beta_{i0r} = \beta_{i0f}$ and $\beta_{i1r} = \beta_{i1f}$. If $\beta_{i1r} \neq \beta_{i1f}$, DIF is said to be nonuniform; and if $\beta_{i0r} \neq \beta_{i0f}$ and $\beta_{i1r} = \beta_{i1f}$, DIF is said to be uniform because the regression functions of reference and focal group only differ in location (difficulty or attractiveness) and not in discrimination. Likelihood ratio tests are used for testing the null hypotheses of equal item parameters across groups.

The Logistic Regression Method treats the test score as a quantitative covariate. In contrast, the Logit Method [13] treats the test score as a nominal variable. The studied item i is deleted from the test, and for each of the examinees (respondents) the rest score, that is, the score on the remaining $n - 1$ items is computed. The sample size per rest score may be too small, and mostly the rest scores are classified

2 Item Bias Detection: Classical Approaches

into a smaller number (three to seven) categories. The Logit Method adapts (2) to the situation of a nominal test score for matching reference and focal group members. Technically, this adaptation is done by using dummy coding (*see Dummy Variables*) of the test score categories and substituting dummy variables for the test score into (2). Likelihood ratio tests for the equality of item parameters across groups are used for the study of nonuniform and uniform DIF.

The Mantel–Haenszel Method [9] uses the test score itself for matching reference and focal group members. The Mantel–Haenszel Method adapts (2) to the situation of a nominal test score by using dummy coding of the test scores and substituting dummy variables for the test score into (2). Moreover, the Mantel–Haenszel Method assumes that DIF is uniform, that is, it sets β_{i1r} equal to β_{i1f} [1]. The Mantel–Haenszel statistic is used for testing the null hypothesis of uniform DIF ($\beta_{i0r} = \beta_{i0f}$). This statistic has some advantages above the likelihood ratio test for uniform DIF. First, the Mantel–Haenszel test is less affected by test scores that have small sample sizes [1]. Second, the test has the largest **power** for testing the null hypothesis $\beta_{i0r} = \beta_{i0f}$ under the assumption $\beta_{i1r} = \beta_{i1f}$. Therefore, the Mantel–Haenszel test is the best test for DIF when it can be assumed that DIF is uniform [5]. However, the test is less appropriate when DIF is nonuniform. The Mantel–Haenszel Method was adapted to a procedure that can detect nonuniform DIF by [12].

The Standardization and SIBTEST methods use the test score for matching reference and focal group members, but they do not use parametric regression functions. The Standardization Method [6] defines the standardization index as

$$SI_i = \sum_x \frac{N_{xf}}{N_f} \{P_{if}(x) - P_{ir}(x)\}, \quad (3)$$

where $\sum_x$ means that the summation is over all observed test scores, N_{xf} is the number of focal group members who have test score x and N_f is the total number of focal group members. Estimates of the index and its variance can be used to test the null hypothesis that the index is 0. The value of SI can be near 0 when positive and negative differences cancel out in (3). Therefore, SI is appropriate when all differences have the same sign across the test scores, which was called unidirectional DIF [17]. Unidirectional DIF means that the item is always

biased against the same group at each of the test scores. However, the SI is less appropriate when $\{P_{if}(x) - P_{ir}(x)\}$ is positive at some test scores and negative at other scores. It is remarked that a uniform DIF item is always a unidirectional DIF item, but a unidirectional DIF item does not need to be a uniform DIF item [8].

The SIBTEST Method for the detection of a DIF item splits the test into a subtest of $n - 1$ items that is used for matching and a single studied item. A modified version of SI is used that compares the probabilities of giving the correct (affirmative) answer of reference and focal group members, given the examinees' (respondents') estimated true scores, where the true scores are estimated separately for the reference and focal group using the CTT regression of true score on observed score.

Ordinal-polytomous Item Responses

The item response variable has C ($C > 2$) ordered categories, for example, a five-point Likert scale ($C = 5$). $P_{icr}(x)$ and $P_{icf}(x)$ are the probabilities of responding in the c th category of the i th item, given the test score, in the reference and focal group, respectively. Under CTT, item i is considered to be free of DIF if these probabilities are equal across all values of the test score, which means that $C - 1$ probabilities must be equal because the C probabilities sum to 1:

$$P_{icr}(x) = P_{icf}(x) = P_{ic}(x), \quad c = 1, 2, \dots, C - 1, \\ \text{for all values } x \text{ of } X. \quad (4)$$

The previously discussed methods for DIF detection of dichotomous items were extended to polytomous items; a framework is given by [15].

The Logit Method was described as a special case of the Loglinear Method for polytomous items (*see Log-linear Models*) [13]. The Logistic Regression Method was extended to the Multiple-Group Logistic Regression Method, which subsumes the Proportional Odds Method as a special case [20]. The Mantel–Haenszel Method was extended to the Generalized Mantel–Haenszel and Mantel Methods [21]. These extended methods treat the test score in the same way as their corresponding methods for dichotomous items: The Loglinear, Generalized Mantel–Haenszel, and Mantel Methods

use the test score as a nominal matching variable, whereas the Multiple-Group Logistic Regression and Proportional Odds Methods use the test score as a quantitative covariate. Moreover, the extended methods differ in the way the categories of the response variable are handled: The Loglinear and Generalized Mantel–Haenszel Methods treat them as nominal categories, the Multiple-Group Logistic Regression and Proportional Odds Methods treat them as ordered categories, and the Mantel Method assigns quantitative values to the ordered categories.

The Standardization and SIBTEST Methods were extended to the Standardized Mean Differences [7, 22] and POLYSIBTEST Methods [3], respectively. Both methods assign quantitative values to the item response categories. The Standardized Mean Differences Method treats the test score as a nominal matching variable, whereas the POLYSIBTEST Method uses the estimated true score per group for matching reference and focal group members.

Comments

The test score is used to correct for ability (trait) differences between reference and focal group. Therefore, the test must predominantly measure one latent construct. Psychometric methods can be used to study the dimensionality of a test, but DIF yields a conceptual problem. A differentially functioning item is by definition multidimensional, for example, a mathematics item may be differentially functioning between native and nonnative speakers because nonnative speakers have difficulty to understand the content of the item. A pragmatic approach to the multidimensionality problem is a stepwise application of DIF detection methods to purify the test [10, 19].

The statistics of the different DIF detection methods are sensitive to different types of DIF, and test different types of null hypotheses. The Logit and Logistic Regression Methods and their extensions are sensitive to both uniform and nonuniform DIF, the Mantel–Haenszel Method and its extensions to uniform DIF, and the Standardization and SIBTEST Methods and their extensions to unidirectional DIF.

From a theoretical point of view, each of the CTT-based methods is flawed. The test score is handled as a nominal matching variable or as a quantitative covariate, but it can better be considered as an ordinal variable [4]. From the CTT perspective, the per group

estimated true score must be preferred for correction of ability (trait) differences, but most of the methods use the test score. Usually, the response categories of a polytomous item are ordinal, but only the Multiple-Group Regression and Proportional Odds Methods treat them correctly as ordered. Theoretically, IRT-based methods (*see Item Bias Detection: Modern Approaches*) should be preferred. However, the application of IRT-based methods requires that a number of conditions are fulfilled. Therefore, CTT-based methods are frequently preferred in practice.

Item Bias Detection: Modern Approaches

In the 1960s, concern was raised on the fairness of educational and psychological tests. It was found that the test performance of American minority group members stayed behind the performance of Whites, and tests were claimed to be biased against minorities [1]. Methods were developed to detect test items that put minority group members at a disadvantage. These methods did not clearly distinguish between impact and item bias. Impact means that between-group item performance differences are explained by between-group ability distribution differences, whereas item bias means that between-group item performance differences exist for examinees of equal ability from different groups. Lord [9] described an **item response theory (IRT)** based item bias detection method, which does not confuse item bias and impact.

The concept of item bias had a rather limited scope. It applied to achievement and ability tests, which consist of dichotomously scored items, and to ethnic, sex, and cultural groups. The concept was broadened into several directions. The term ‘item bias’ was replaced by the more neutral term ‘**differential item functioning**’ (DIF); DIF was extended from achievement and ability tests to attitude and personality questionnaires, from dichotomously scored item responses to other response scales, and from a group membership variable to other types of variables that may affect item responses; and DIF was subsumed under the general concept of ‘measurement invariance’ (MI) [13, 14].

DIF Definition

Mellenbergh [11] gave a definition of an unbiased item, which subsumes item bias under the more general MI definition. This definition is adapted to the situation of a unidimensional test (questionnaire), which is intended to measure one latent variable Θ . The observed item response variable is indicated by I , and the unintended variable which may affect the item responses is called the *violation* V [18]. The definition of a non-DIF item is:

Item i for the measurement of the **latent variable** Θ is not differentially functioning with respect to the potential violator V , if and only if

$$f(I_i|\Theta = \theta, V = v) = f(I_i|\Theta = \theta) \quad (1)$$

for all values θ of Θ and v of V , where $f(I_i|\Theta = \theta, V = v)$ is the conditional distribution of the responses to the i th item given the latent variable and the violator and $f(I_i|\Theta = \theta)$ is the conditional distribution of the responses to the i th item given only the latent variable; otherwise, item i is differentially functioning with respect to V .

Equation (1) means that, given the intended latent variable, the item responses and the potential violator are independently distributed. This definition is very general. It is assumed that I is intended to measure one latent variable Θ , but it does not make any other assumption on I , Θ , and V , for example, V can be an observed or a latent variable [8].

Modern (IRT) DIF detection methods are based on this definition. The general strategy is to check whether (1) applies to observed item responses. In practice, specifications must be made. Some well-known DIF situations are discussed. For each of these specifications, the latent variable is a continuous variable, that is, a latent trait; and the violator, a nominal (group membership) variable; a group of special interest (e.g., Blacks) is called the *focal group* ($V = f$) and the group with whom the focal group is compared (e.g., Whites) is called the *reference group* ($V = r$). For this situation, (1) converts into:

$$\begin{aligned} f(I_i|\Theta = \theta, V = r) &= f(I_i|\Theta = \theta, V = f) \\ &= f(I_i|\Theta = \theta). \end{aligned} \quad (2)$$

Dichotomous Item Responses

The item response is dichotomously scored: $I = 1$ for a correct (affirmative) answer and $I = 0$ for an incorrect (negative) answer. It is assumed that the item responses are, conditionally on the latent trait, Bernoulli distributed with parameters $P_{ir}(\theta)$ and $P_{if}(\theta)$ of giving the correct (affirmative) answer to the i th item in the reference and focal group, respectively. The $P_{ir}(\theta)$ and $P_{if}(\theta)$ are the regression functions of the observed item response on the latent trait, that is, $P_{ir}(\theta) = E(I_i|\Theta = \theta, V = r)$ and $P_{if}(\theta) = E(I_i|\Theta = \theta, V = f)$, and are called *item response functions* (IRFs).

2 Item Bias Detection: Modern Approaches

Figure 1 Examples of (a) unidirectional and (b) bidirectional DIF

A Bernoulli distribution (*see Catalogue of Probability Density Functions*) is completely determined by its parameters. Therefore, (2) is equivalent to:

$$P_{ir}(\theta) = P_{if}(\theta) = P_i(\theta). \quad (3)$$

Equation (3) states that the IRFs of the reference and focal group are equal. The general strategy of DIF detection is to check whether (3) holds across the values of the latent trait.

If (3) does not hold, item i is differentially functioning between reference and focal group. Equation (3) can be violated in different ways, and different types of DIF can be distinguished [4, 5], for example unidirectional and bidirectional DIF [22]. Unidirectional DIF means that the IRFs of the reference and focal group do not intersect (Figure 1(a)), whereas bidirectional DIF means that the two IRFs intersect at least once (Figure 1(b)).

Unidirectional DIF implies that any bias of the item is always against the same group, whereas bidirectional DIF implies that the item is biased against one group for some values of the latent trait and biased against the other group for other values of the latent trait.

Nonparametric Item Response Theory models do not use parameters to characterize the IRF. Mokken's [15, 16] nonparametric double monotonicity model (DMM) can be used to study between-group DIF. The DMM assumes that the IRF is a nonparametric monotonically nondecreasing function of the latent trait, and that the IRFs of the n items of a test (questionnaire) do not intersect; an example is shown in Figure 1(a). Methods to detect DIF under the DMM are described by [23].

Parametric IRT models specify IRFs that are characterized by parameters; models that specify a normal ogive or logistic IRF are discussed by [3] and [10]. These IRFs are characterized by one-, two-, or three-item parameters; DIF is studied by testing null hypotheses on these parameters. An example of a parametric IRF is Birnbaum's [2] two-parameter logistic model (2PLM):

$$P_i(\theta) = \frac{e^{a_i(\theta - b_i)}}{1 + e^{a_i(\theta - b_i)}}, \quad (4)$$

where a_i is the item discrimination parameter and b_i is the item difficulty (attractiveness) parameter.

Under the 2PLM, the definition of a non-DIF item (3) is satisfied if the item parameters of the reference and focal group are equal, that is, $a_{ir} = a_{if}$ and $b_{ir} = b_{if}$. Lord [10] developed a chi-square test for the null hypothesis of equal item parameters across groups, and a likelihood ratio test for this null hypothesis is given by [24]. An overview of statistics for testing the null hypothesis of equal item parameters under IRT models for free-answer and multiple-choice items is given by [26].

The rejection of the null hypothesis of equal item parameters means that the item is differentially functioning between reference and focal group, but it does not show the amount of DIF. Three different types of DIF-size measures were described in the literature. The first type quantifies the amount of DIF at the item level [19, 20]. The signed area measure is the difference between the two IRFs across the latent trait:

$$SA_i = \int_{-\infty}^{\infty} \{P_{if}(\theta) - P_{ir}(\theta)\} d\theta. \quad (5)$$

Under some IRT models (e.g., the 2PLM), DIF can be bidirectional. The SA measure can be near 0 for intersecting IRFs when positive and negative differences cancel each other out; the unsigned area measure is the distance (area) between the two IRFs:

$$UA_i = \int_{-\infty}^{\infty} |P_{if}(\theta) - P_{ir}(\theta)| d\theta. \quad (6)$$

The SA and UA measures assess DIF size at the item level, but they do not show the effect of DIF at the examinees' (respondents') level. The second type of DIF-size measures [28] combines DIF at the item level with the latent trait distribution of the focal group. Some of the items of a test (questionnaire) can be biased against the focal group, whereas other items can be biased against the reference group, which means that bias can compensate within a test (questionnaire). Therefore, a DIF-size measure that is compensatory within a test (questionnaire) was developed by [21].

Ordinal-polytomous Item Responses

The item response variable has C ($C > 2$) ordered categories, for example, a five-point Likert scale ($C = 5$). It is assumed that the item responses are, conditionally on the latent trait, multinomially distributed with probabilities $P_{icr}(\theta)$ and $P_{icf}(\theta)$ of answering in the c th category ($c = 1, 2, \dots, C$) in the reference and focal group, respectively.

A C -category multinomial distribution is completely determined by $C - 1$ probabilities because the C probabilities sum to 1. Therefore, the definition of a non-DIF item (2) is equivalent to

$$P_{icr}(\theta) = P_{icf}(\theta) = P_{ic}(\theta), c = 1, 2, \dots, C - 1. \quad (7)$$

Parametric IRT models were defined for these probabilities under the constraint that the ordered nature of the C categories is preserved [27]. DIF detection proceeds by testing the null hypothesis of equal item parameters across the reference and focal group.

Continuous Item Responses

The item response is on a continuous scale, for example, the distance to a mark on a line. It is

assumed that the item responses are, conditionally on the latent trait, normally distributed. This assumption may be violated in practical applications because response scales are usually bounded (e.g., a 4-inch line segment).

A normal distribution is completely determined by its mean and variance. Therefore, (2) is equivalent to:

$$\begin{aligned} E(I_i | \Theta = \theta, V = r) &= E(I_i | \Theta = \theta, V = f) \\ &= E(I_i | \Theta = \theta), \end{aligned} \quad (8a)$$

$$\begin{aligned} Var(I_i | \Theta = \theta, V = r) &= Var(I_i | \Theta = \theta, V = f) \\ &= Var(I_i | \Theta = \theta), \end{aligned} \quad (8b)$$

where Var denotes variance. A unidimensional latent trait model for continuous item responses is the model for congeneric measurements [6], which is Spearman's one-factor model applied to item responses [12]. The one-factor model specifies three item parameters: the intercept (difficulty or attractiveness), loading (discrimination), and residual variance. The definition of a non-DIF item (8) is satisfied if the parameters of the reference and focal group are equal; null hypotheses on the equality of item parameters can be tested using multiple group **structural equation modeling (SEM)** methods [7].

The Underlying Variable Approach

The previously mentioned DIF detection methods are based on IRT models that directly apply to the observed item responses. However, within the SEM context, an indirect approach to dichotomous and ordinal-polytomous variables is known [7]. It is assumed that a continuous variable underlies a discrete variable and that this continuous variable is divided into two or more categories. Spearman's one-factor model is applied to the underlying response variables, and the equality of the factor model item parameters across the reference and focal group is tested [17].

Test Purification

The null hypothesis of equal item parameters is tested for an item that is studied for DIF. However, the item parameters of the other $n - 1$ test (questionnaire) items are constrained to be equal across the two

groups. A conceptual problem of DIF detection is that the constraints may be incorrect for one or more of the $n - 1$ other items. This problem is handled by using a stepwise or anchor test method. The stepwise procedure purifies the test (questionnaire) by removing DIF items in steps [10]. The anchor test method allocates a part of the n items to an anchor test, which is free of DIF [25]. The bottleneck of the anchor test method is the choice of the anchor items because these items must be free of DIF. Classical (test theory-based) DIF detection methods can be used to select non-DIF anchor items (Mellenbergh, this volume).

Item Exposure

Major professional organizations [1, 3] clearly stress in their guidelines that, to ensure the validity of test scores, it is critical that all aspects of test security be taken into account as tests are developed and delivered. According to these guidelines, three principal aspects of test security need to be addressed. First, test materials (e.g., test booklets and their associated keys stored in paper or electronic form) must be kept secure throughout test development and administrations, until they are released to the public. Second, cheating must be prevented during test administration. And third, the possibility for examinees to gain specific knowledge about items to be used in future administrations, through past administrations (and possibly pretesting), must be minimized. The focus of this entry is on this third aspect of test security.

Consider item exposure (or simply exposure), which reflects the extent to which an item has been used in past administrations, as an indicator of how much risk there is that it has been compromised for future administrations. That risk depends on future examinees' ability, individually through past testing experience or collectively through organized or informal networks, to recollect and gather detailed information on items used or reused in past administrations. It also depends on the extent to which future exposure is predictable, allowing examinees to focus their preparation on items identified as likely to appear in the test and even memorize answers keys, and as a result, obtaining scores significantly different from the ones they would have obtained under the standardized conditions test users expect. Worse, coaching organizations or dedicated internet web sites may actually engage in concerted efforts to gain and disseminate highly accurate information to their clients and distort testing outcomes for small or large subpopulations.

Of course, the most effective way to avoid this problem is not to reuse items at all. However, increasingly, testing clients are demanding greater scheduling flexibility and shorter testing time, which are generally attainable only through higher administration frequency and more efficient tests designs. Unfortunately, for many testing programs, this strategy is not viable. Given that the amount of work and the costs involved in developing new items are largely

incompressible, increasing testing frequency (resulting in fewer examinees per administration to share the costs) quickly results in resource requirements far exceeding what an organization or its clients can afford. And, although shorter test length could in principle decrease item needs, in practice this has not happened because to maintain measurement accuracy tests have to rely more heavily on highly informative items that have to be 'cherry picked.'

When item reuse is necessary, maintaining test security requires: (a) the establishment of acceptable item exposure limits, (b) the implementation of effective test design and development procedures to maintain exposure below the acceptable limits, (c) the monitoring of item-measurement properties and examinee scores over administrations, and (d) the monitoring of examinee information networks (e.g., internet websites) for evidence of security breach.

Although no firm guideline exists for determining acceptable exposure limits, values used by existing programs may be considered [5] and item memorization or 'coachability' studies may be conducted. Once in operation, these limits may be further established as monitoring information becomes available.

This entry provides a brief description of measures useful for monitoring item exposure and evaluating test security. Then it discusses alternative traditional linear (TL), multistage (MST) or **computerized adaptive testing (CAT)** test design choices as they relate to exposure. And finally, it outlines the methodologies that can be employed to maintain acceptable item exposure rates.

Evaluation and Monitoring of Item Exposure

The most obvious way to measure item exposure is to keep track of the total number of times an item has been administered. However, this measure alone may not be a sufficient indicator of the security risk an item presents for future test administrations. Additional measures, including exposure rate, conditional exposure rate and test overlap, are also useful for deciding if an item can be safely included in new test forms, if it should be set aside or 'docked' for a period of time before it is made available for testing again, or if it is time to retire it. On the basis of these measures, operational item-screening rules

2 Item Exposure

and algorithms can be devised to effectively manage the operational item bank and assemble new test forms [8].

Let's call X the total number of times an item has been administered. If X_M represents the maximum acceptable number of exposures, then item j should be retired whenever $X_j > X_M$.

Furthermore, an item that tends to be seen by larger proportions of examinees is more likely to become known in greater detail even before it reaches X_M than another one seen by only few of the examinees taking the test. Considering n_j the number of examinees who have seen item j and N the total number of examinees who have been tested during a given time period, the item's exposure rate for that time period is simply: $x_j = n_j/N$. If x_M represents the maximum acceptable exposure rate over the last time period, then item j should be docked whenever $x_j > x_M$.

To illustrate how these measures and criteria may be applied, let us imagine three items and follow their exposure over six administration cycles, during each of which tests are drawn from a new item pool following a typical CAT design. Figure 1 displays the three-item exposure rates and the maximum acceptable limit x_M . It shows that during the first administration cycle, item 3 was highly exposed at a 0.6 rate, coming close to the maximum acceptable exposure, say $X_M = 7000$, as a result of 10 000 administrations. Because of that, the item was retired. Item 2 was exposed at a much lower rate: first below $x_M = 0.3$, then slightly above x_M and consequently docked for the next cycle, then still slightly above x_M reaching X_M to be finally retired. Item 1, exposed at an even lower rate, was used throughout.

Figure 1 Exposure rates and maximum acceptable limit for three items

Conditional exposure and test-overlap measures may also be needed in order to effectively manage test security [5]. Conditional measures in particular may be necessary for programs using adaptive testing (CAT or MST). Because adaptive testing seeks to match item difficulty with examinee performance (oftentimes through maximizing item information), for some items, exposure can become very high among examinees of similar ability while their overall exposure is below the acceptable limit or even quite low. Moreover, the security risk associated with high conditional exposure amongst, for example, the most able examinees may not be limited to that group as information sharing is likely to go across ability groups. Although there is the added complexity of having to evaluate exposure across multiple groups, conditional exposures can be evaluated essentially the same way overall measures are.

Concerning test overlap, if the proportion of items shared between any two test forms is large, then examinees who retake the test may be unduly advantaged as they may have already experienced a large proportion of the test items. However, overlap can be tedious and difficult to keep track of. Fortunately, Chen and Ankenmann [2] have shown that there is a very strong relationship between the easy-to-measure exposure rates and test overlap and they have provided an easy way to estimate overall or conditional test overlap based on overall or conditional exposure rates. From a practical point of view, it might be more meaningful to set item test overlap rather than item exposure limits. Therefore, overlap may be used instead of, or as a complement to, exposure for evaluating, implementing, and monitoring test security.

Test Design and Item Exposure

Options for test design are numerous. Choosing an appropriate test design involves evaluating alternatives and making trade-offs between many competing goals, one of which is maintaining test security through exposure control. The purpose of this section is to briefly review various aspects of test design as they may facilitate or impede exposure control.

From this point of view, the most important aspects of test design include its administration schedule, length, and degree of adaptation to examinees. The administration schedule may be defined by

its frequency and by the number of alternative forms used during each administration occasion or cycle. On the one end, occasional administration of a single test form (at say a couple of dates per year) may not require any item reuse. On the other end, continuous administration with as many forms as examinees assembled from the same item pool is only possible with item reuse. However, it is worth noticing that higher administration frequency, in addition to providing scheduling flexibility, may also allow for more effective exposure management as items use may be spread across many more forms and their future rendered less predictable. This is discussed further in the next section.

The situation with test length is less intuitive. *A priori* a smaller test length would ease item demand and reduce the need for item reuse. But, experience has shown that significant length reduction tends to greatly increase the demand on the most informative items (in order to maintain test-reliability requirements) and practically disqualify large numbers of medium- to low-information items from being usable. Unchecked, this can lead to both the overexposure and depletion of the most sought after items, jeopardizing not only the security but also the psychometric quality of the tests produced.

Test adaptation is another important aspect of test design. By tailoring tests to examinees, there is some potential for more secure and more efficient testing. Indeed, with the traditional linear design (nonadaptive), test forms have to include items that cover a wide range of abilities, including items that after the fact will be of little value for the estimation of the examinee's score. With CAT, the increasingly precise ability estimations that can be made as testing progresses can be used to make more judicious item selections. By avoiding items too easy or too difficult, items for one examinee but useful to other examinees, CAT and to a certain extent MST may in fact provide greater testing flexibility and reduce testing time without the need for more item development.

Methods for Controlling Item Exposure

For any given design, test development can be viewed as a three-step process, with exposure control measure taking part in each one of these steps. In the first step, newly developed items are added to

the operational bank and existing items are screened through the application of the docking and retirement rules (as discussed earlier). With the TL test design, in the second step, a specified number of parallel forms are assembled. And finally, the assembled forms are randomly administered to examinees until the next test development cycle. In that case, either or both more stringent bank-screening rules and larger number of forms will lead to reduced item exposures. Also, because forms are assembled in advance of administration, there is no interaction between examinee performance and test assembly; thus, conditional exposure is not an issue.

With adaptive testing, in the second step, instead of test forms, one or more item pools are assembled. And, finally from each randomly assigned pool tests are assembled and administered (generally on-demand but not necessarily) to examinees. As with linear testing, exposure can be controlled primarily through bank management (first step) and through the use of multiple parallel pools. However, because pools generally need to be large, the number of parallel pools that can be used within the same administration cycle is often very limited. An additional challenge with adaptive testing may also arise from its emphasis on shortening test length and maximizing measurement efficiency. Many of the adaptive test assembly algorithms that have been developed tend to rely heavily on the most informative items available resulting in only a small proportion of any pool being used (exposed) at a high rate overall and at very high rates conditionally.

In assembling tests from an item pool, two main approaches have been developed in order to strike a balance between the need for exposure control and the desire for measurement efficiency. The first approach is to partition (stratify) the pool to create subsets of items with similar characteristics that can be selected interchangeably (e.g., through a purely random process). In that way, exposure is spread evenly among all the items available within each subgroup and exposure rates are determined by the subgroup size and the number of times, within each test assembly, items are selected from the subgroup. However, effective implementation may require a relatively complex partitioning of the pool (e.g., based on item discrimination and difficulty as well as item content). Yi and Chang [9] provide further discussion and an example of implementation of this approach.

The second approach is based on a probabilistic control of the item selection during test assembly. With that approach, the selection algorithm first determines the best items available to maximize measurement efficiency. Then, starting with the best item, a random number is drawn and compared with the item probability parameter resulting in either its rejection (without replacement) and the trial selection of the next best item or its selection; the selection being done with the first accepted item. Before operational use, this approach requires the repeated simulations of large number of tests in order to find, by successive adjustment, the item exposure control parameters that will result in exposures below the desired limits. Stocking and Lewis [5] and van der Linden [7] provide further discussions and examples of implementation of this approach.

Conclusion

For most testing programs, ensuring appropriate exposure control without compromising measurement requires choices of appropriate test design and exposure control mechanisms as well as significant test development efforts renewed over each test administration cycle. For further information, the two recent and complementary books, 'Computerized Adaptive Testing: Theory and Practice' [6] and 'Computer-based Testing: Building the Foundation for Future Assessment' [4], are primary sources to be consulted as they provide broad and practical as well as in-depth treatment of test development and exposure control issues.

Item Response Theory (IRT): Cognitive Models

That **item response theory (IRT)** was called latent trait theory into the 1980s reflects its origins in trait psychology. By modeling response probabilities at the level of items rather than test scores, IRT provided practical solutions to thorny problems in classical test theory, including item banking, adaptive testing, and linking tests of different lengths or difficulties. But operationally, the person parameter in IRT models (usually denoted θ) was essentially the same as that of true score in classical test theory, namely, a propensity to perform well in some domain of tasks. The meaning of that propensity lay outside IRT, and was inferred from the content of the tasks.

The ‘cognitive revolution’ of the 1960s and 1970s, exemplified by Newell and Simon’s *Human Information Processing* [20], called attention to the nature of knowledge, and the ways in which people acquire and use it. How do people represent the information in a situation? What operations and strategies do they use to solve problems? What aspects of problems make them difficult, or call for various kinds of knowledge or processes? Researchers such as Carroll [4] and Sternberg [27] studied test items as psychological tasks. Others, including Whitely [29]¹ and Klein et al. [15] designed aptitude and achievement test items around features motivated by theories of knowledge and performance in a given domain.

Several psychometric models have been introduced to handle claims cast in information-processing terms, explicitly modeling performance in terms of theory-based predictions of performance. Cognitively based IRT models incorporate features of items that influence persons’ responses, and relate these features, through θ , to response probabilities. Examples of IRT models that incorporate cognitively motivated structures concerning task performance are presented below (see [13] for a more detailed discussion of building and estimating such models).

Measurement Models

In a basic IRT model for dichotomous items, θ represents person proficiency in the domain, and the observable variables ($X_1, \dots, X_n$) are responses to

n test items. Possibly vector-valued item parameters ($\beta_1, \dots, \beta_n$) determine the conditional probabilities of the X s given θ . Under the usual IRT assumption of **conditional independence**,

$$P(x_1, \dots, x_n | \theta, \beta_1, \dots, \beta_n) = \prod_{j=1}^n P(x_j | \theta, \beta_j). \quad (1)$$

Under the **Rasch model** [22] for dichotomous items, for example,

$$P(x_j | \theta, \beta_j) = \begin{cases} \Psi(\theta - b_j) & \text{if } x_j = 1 \\ 1 - \Psi(\theta - b_j) & \text{if } x_j = 0 \end{cases}, \quad (2)$$

where $\Psi(\cdot) \equiv \exp(\cdot) / [1 + \exp(\cdot)]$ is the cumulative logistic probability distribution, θ is a one-dimensional measure of proficiency, b_j is the difficulty of item j , and x_j is 1 if right and 0 if wrong. This formulation does not address the nature of θ , the rationale for the difficulty of item j , or the connection between the two.

Linear Logistic Test Model (LLTM)

In the Linear Logistic Test Model (LLTM; [6, 25]), cognitively based features of items and persons’ probabilities of response are related through a Q -matrix [28], where q_{jk} indicates the degree to which feature k applies to item j . In simple cases, q_{jk} is 1 if feature k is present in item j and 0 if not. The LLTM extends the Rasch model by positing a linear structure for the b_j s:

$$b_j = \sum_k q_{jk} \eta_k = q'_j \eta, \quad (3)$$

where η_k is a contribution to item difficulty entailed by feature k . Features can refer to a requirement for applying a particular skill, using a particular element of information, carrying out a procedure, or some surface feature of an item.

Fischer [6] used the LLTM to model the difficulty of multistep calculus items, as a function of how many times each of seven differentiation formulas had to be applied. Hornke and Habon [9] generated progressive matrix items in accordance with the rules of the patterns across stimuli, and modeled item difficulty in these terms. Sheehan and Mislevy [26] fit an LLTM-like model with random item effects, using features based on Mosenthal and Kirsch’s [17] cognitive analysis of the difficulty of document

literacy tasks. The features concerned the structure of a document and the complexity of the task to be performed. In each of these applications, any given value of θ can be described in terms of expected performance in situations described by their theoretically relevant features.

Multidimensional Cognitive IRT Models

Providing theoretically derived multidimensional characterizations of persons' knowledge and skills is called cognitive diagnosis [21]. Most cognitively based **multidimensional item response theory (IRT) models** posit either compensatory or conjunctive ('noncompensatory') combinations of proficiencies.

Compensatory Models. In compensatory models, proficiencies combine linearly, so a lack in one proficiency can be made up with an excess in another proficiency, that is, $a'_j\theta = a_{j1}\theta_1 + \dots + a_{jD}\theta_D$, where θ is a D -dimensional vector. The a_{jd} s indicate the extent to which proficiency d is required to succeed on item j . The A -matrix is analogous in this way to the Q -matrix decomposition of examinee proficiencies. A is estimated in some models [1], but in applications more strongly grounded in cognitive theory they are treated as known, their values depending on the knowledge and skill requirements that have been designed into each item. For example, Adams et al.'s [2] Multidimensional Random Coefficients Multinomial Logit Model (MRCMLM) posits known a_{dk} s and q_{jk} s. The probability of a correct response for a dichotomous item is

$$\Pr(X_j = 1 | \theta, \eta, a'_j, q'_j) = \Psi(a'_j\theta + q'_j\eta). \quad (4)$$

When the MRCMLM is applied to polytomous responses, each response category has its own a and q vectors to indicate which aspects of proficiency are evidenced in that response and which features of the category context contribute to its occurrence. Different aspects of proficiency may be involved in different responses to a given item, and different item features can be associated with different combinations of proficiencies. Adams et al. provide an example with a mathematical problem-solving test using the structure of learning outcome (SOLO) taxonomy; constructed responses are scored according to an increasing scale of cognitive complexity, and the θ s indicate persons' propensities to give explanations

that reflect these increasing levels of understanding. De Boeck and his students (e.g., [10, 12, 23]) have carried out an active program of research using such models to investigate hypotheses about the psychological processes underlying item performance.

Conjunctive Models. In conjunctive models, an observable response is the (stochastic) outcome of sub processes that follow unidimensional IRT models. Embretson [5] describes a multicomponent latent trait model (MLTM) and a general component latent trait model (GLTM) in which distinct subtasks are required to solve a problem, and the probability of a success in each depends on a component of θ associated with that subtask. An 'executive process' parameter e represents the probability that correct subtask solutions are combined appropriately to produce an overall success, and a 'guessing' parameter c is the probability of a correct response even if not all subtasks have been completed correctly. An example of the MLTM with $e = 1$ and $g = 0$ models the probability that an examinee will solve an analogy item as the product of succeeding on Rule Construction and Response Evaluation subtasks, each modeled by a dichotomous Rasch model:

$$P(x_{jT} = 1 | \theta_1, \theta_2, \beta_{j1}, \beta_{j2}) = \prod_{m=1}^2 \Psi(\theta_m - \beta_{jm}), \quad (5)$$

where x_{jT} is the overall response, θ_1 and β_{j1} are examinee proficiency and Item j 's difficulty with respect to Rule Construction, and θ_2 and β_{j2} are proficiency and difficulty with respect to Response Evaluation. Under the GLTM, both subtask difficulty parameters β_{j1} and β_{j2} can be further modeled in terms of item features as in the LLTM.

Hybrids of IRT and Latent Class Models

Latent class models are not strictly IRT models because their **latent variables** are discrete rather than continuous. But some cognitively based IRT models incorporate a particular latent class model called 'binary skills' models [7, 16]. In a binary skills model, there is a one-to-one correspondence between the features of items specified in a Q -matrix and elements of peoples' knowledge or skill, or 'cognitive attributes'. A person is likely to answer item j

correctly if she possesses all the attributes an item demands and incorrectly if she lacks some. Junker and Sijtsma [14] describe two ways to model these probabilities: DINA (Deterministic Inputs, Noisy And) and NIDA (Noisy Inputs, Deterministic And). Under DINA, the stochastic model comes after the combination of the attributes; a person with all necessary attributes responds correctly with probability π_{j1} , and a person lacking some attributes responds correctly with probability π_{j0} :

$$\begin{aligned} \Pr(X_{ij} = 1 | \theta_i, q_j, \pi_{j1}, \pi_{j0}) \\ = \pi_{j0} + (\pi_{j1} - \pi_{j0}) \prod_k \theta_{ik}^{q_{jk}}, \end{aligned} \quad (6)$$

where θ_{ik} is 1 if person i possesses attribute k and 0 if not. Under NIDA, there is a stochastic mechanism associated with each attribute; if attribute k is required by item j (i.e., $q_{jk} = 1$), the contribution to person i being able to solve the item will require either her having attribute k or, if not, circumventing the requirement with probability r_{jk} :

$$\Pr(X_{ij} = 1 | \theta_i, q_j, r_j) = \prod_k r_{jk}^{(1-\theta_{ik})q_{jk}}. \quad (7)$$

Latent variable models for cognitive diagnosis such as DINA and NIDA models have the aim of diagnosing the presence or absence of multiple fine-grained skills required for solving problems. In other words, does the examinee show ‘mastery’ or ‘nonmastery’ of each skill?

Two cognitively based models that combine features of IRT models and binary skills models are the Rule Space model [28] and the Fusion model [8]. Under Rule Space, response vectors are mapped into a space of IRT estimates and fit indices. This includes response patterns predicted by particular configurations of knowledge and strategy – both correct and incorrect rules for solving items – as characterized by a vector of cognitive attributes. The distance of a person’s observed responses from these ideal points are estimated, and the best matches suggest that person’s vector of attributes. Under the Fusion model, a NIDA model is posited for the effect of attributes, but an IRT-like upper bound is additionally proposed; a maximum probability π_{j1} times a probability that depends on a continuous person proficiency parameter ϕ_i and item difficulty b_j that concern knowledge and ability other than those modeled in terms of

attributes:

$$\begin{aligned} \Pr(X_{ij} = 1 | \theta_i, \phi_i, \pi_{j1}, q_j, r_j, b_j) \\ = \pi_{j1} \text{Logit}(\theta_i - b_j) \prod_k r_{jk}^{(1-\theta_{ik})q_{jk}}. \end{aligned} \quad (8)$$

Mixtures of IRT Models and Multiple Strategies

Different students can bring different problem-solving strategies to an assessment setting. Further, comparisons of and theories concerning experts’ and novices’ problem-solving suggest that the sophistication with which one chooses and monitors strategy use, develops as expertise grows. Thus, strategy use is a potential target of inference in assessment. Junker [13] distinguishes four cases for modeling differential strategy use

Case 0: No modeling of strategies (basic IRT models).

Case 1: Model strategy changes between persons.

Case 2: Model strategy changes between tasks within persons.

Case 3: Model strategy changes within task within persons.

Multiple-strategy models incorporate multiple $\mathcal{Q}$ -matrices in order to specify the different strategies that are used to solve the test items. IRT mixture models have been proposed for Case 1 by Rost [24] and Mislevy and Verhelst [18]. Consider the case of M strategies; each person applies one of them to all items, and the item difficulty under strategy m depends on features of the task that are relevant under this strategy in accordance with an LLTM structure, so that the difficulty of item i under strategy m is $b_{jm} = \sum_k q_{jmk} \eta_{mk}$. Denoting the proficiency of person i under strategy m as θ_{im} and ϕ_{im} as 1 if she uses strategy m and 0 if not, the response probability under such a model takes a form such as

$$\begin{aligned} \Pr(X_{ij} = 1 | \theta_i, \phi_i, q_j, \Gamma) \\ = \prod_m \phi_i \left[\Psi \left(\theta_{im} - \sum_k q_{jmk} \eta_{mk} \right) \right]^{x_{ij}} \\ \times \left[1 - \Psi \left(\theta_{im} - \sum_k q_{jmk} \eta_{mk} \right) \right]^{1-x_{ij}} \end{aligned} \quad (9)$$

Huang [11] used a Rasch model studied by Andersen [3] for an analysis under Case 2. His example concerns three approaches to force and motion

problems: Newtonian, impetus theory, and nonscientific response. The response of Examinee i to item j is coded as 1, 2, or 3 for the approach used. Each examinee is characterized by three parameters θ_{ik} , indicating propensities to use each approach, and each item is characterized by three parameters indicating propensities to evoke each approach. Strategy choice is modeled as

$$\Pr(X_{ij} = k | \theta_i, \beta_j) = \frac{\exp(\theta_{ik} - \beta_{jk})}{\sum_{m=1}^3 \exp(\theta_{im} - \beta_{jm})}. \quad (10)$$

Conclusion

As assessments address a more diverse and ambitious set of purposes, there comes an increasing need for inferences that can address complex task performance and instructionally useful information. Cognitively based assessment integrates empirically based models of student learning and cognition with methods for designing tasks and observing student performance, with procedures for interpreting the meaning of those observations [19].

Item Response Theory (IRT) Models for Dichotomous Data

Classical test theory (CTT) (*see* **Classical Test Models**) models have been valuable to test developers and researchers for over 80 years, but today, because of several important shortcomings, they are being replaced by item response theory (IRT) models in measurement practices. In this entry, several shortcomings of classical test theory are highlighted, and then IRT and several promising IRT models for the analysis of dichotomously scored item response data are introduced. Brief discussions of IRT model parameter estimation, model fit, and software are described. Finally, several important applications are introduced.

Strengths and Weaknesses of Classical Test Theory

CTT has been used in the test development field for over 80 years. The testing and assessment field is full of examples of highly reliable and valid tests based on CTT models and principles, and these tests have been used to produce research findings in thousands and thousands of studies (*see* **Classical Test Models**). References to the CTT model with a focus on true score, observed score, and error score, the use of item difficulty (P values) and item discrimination indices (r values) in test development, corrected split-half reliabilities and coefficient alphas, applications of the Spearman–Brown formula and the formula linking test length and validity, corrections to correlations for range restriction, the standard error of measurement, and much more (*see*, for example, [3, 8]) are easily found in the psychometric methods literature.

There will be no bashing in this entry of classical test theory and common approaches to test development and validation. Were these approaches to be used appropriately by more test developers, tests would be uniformly better than they are today, and the quality of research using educational and psychological tests would be noticeably better too.

At the same time, it is clear that classical test theory and related models and practices have some

shortcomings, and so they are not well suited for some of the demands being placed on measurement models today by two innovations: item banking and **computer adaptive testing** (*see*, for example, [1, 9, 11, 13]). One shortcoming is that classical item statistics are dependent on the particular choice of examinee samples. This shortcoming makes classical item statistics (such as item difficulty levels, and biserial and **point biserial correlations**) problematic in an item bank unless all of the test item statistics are coming from equivalent examinee sample, which of course, is highly unrealistic, and to make such a requirement would lower the utility of item banks in test development (the option must be available to add new test items over time to meet demands to assess new content, and to replace overused test items).

A second shortcoming is that examinee scores are highly dependent on the particular choice of items in a test. Give an ‘easy’ set of items to examinees and they will generally score high, and give a ‘hard’ set of items to them, and they will generally score lower. This dependence of test scores on items in a test creates major problems when computer-adaptive testing (CAT) is used. In principle, in a CAT environment (*see* **Computer-Adaptive Testing**), examinees will see items ‘pitched’ or ‘matched’ to their ability levels, and so, in general, examinees will be administered ‘nonparallel’ tests and the test scores themselves will not provide an adequate basis for comparing examinees to each other or even to a set of norms or performance standards set on a nonequivalent form or version of the test.

These two shortcomings are serious drawbacks to the use of classical test theory item statistics with item banking and computer-adaptive testing but there are more. Typically, classical test models provide only a single estimate of error (*i.e.*, the standard error of measurement) and it is applied to the test scores of all examinees. (It is certainly possible to obtain standard errors conditional on test score but this is rarely done in practice.) But this means that the single error estimate for a test is probably too large for the bulk of ‘middle ability examinees’ and too small for examinees scoring low or high on the ability scale. Also, CTT models the performance of examinees at the test score level (recall ‘test score = true score + error score’) but CAT requires modeling between examinee ability and items so that optimal item selections can be made. Finally, items and examinees are reported on separate, and noncomparable scales

in classical measurement (items are reported on a scale defined over a population of examinees, and examinees are reported on a scale defined for a domain of content). This makes it nearly impossible to implement optimal assessment where items are selected to improve the measurement properties of the test for each examinee, or a prior ability distribution.

IRT Models, Assumptions, and Features

Item response theory is a statistical framework for linking examinee scores to the items on a test to the trait or traits (usually called ‘abilities’) that are measured by that test. Abilities may be narrow or broad; they might be highly influenced by instruction (e.g., math skills) or more general human characteristics (e.g., cognitive functioning); and they might be in the cognitive, affective, or psychomotor domains. These abilities could be unidimensional or multidimensional too but only unidimensional abilities will be considered further in this entry (see **Multidimensional Item Response Theory Models**, and [12]).

A mathematical model must be specified that provides the ‘link’ (for example, the three-parameter logistic model) between these item scores and the trait or ability measured by the test. Nonlinear models have been found to better fit test data, and so there has rarely been interest in linear models, or at least not since about 1950. It is common to assume there is a single unidimensional ability underlying examinee item performance, but models for handling multiple abilities are readily available (see **Multidimensional Item Response Theory Models**, [12]). With a nonlinear model specified, and the examinee item scores available, examinee and item parameters can be estimated.

A popular IRT model for handling dichotomously scored items is the three-parameter logistic test model:

$$P_i(\theta) = c_i + (1 - c_i) \frac{e^{Da_i(\theta - b_i)}}{1 + e^{Da_i(\theta - b_i)}}, i = 1, 2, \dots, n. \quad (1)$$

Here, $P_i(\theta)$ is the probability of an examinee providing the correct answer to test item i , and this nonlinear probability function of θ is called an *item characteristic curve* (ICC) or item characteristic function (ICF). The probability is defined either over administrations of items equivalent to test item i

to the examinee, or defined for a randomly drawn examinee with ability level θ . Item parameters in this model are denoted b_i , a_i , and c_i , and described by test developers as item difficulty, item discrimination, and pseudoguessing (or simply, guessing), respectively. The pseudoguessing parameter in the model is the height of the lower asymptote of the ICF introduced in the model to fit the nonzero performance of low performing examinees, perhaps due to random guessing. The b-parameter is located on the ability scale at a point corresponding to a probability of $(1 + c_i)/2$ of a correct response (thus, if $c = .20$, then the b-parameter corresponds to the point on the ability continuum where an examinee has a .60 probability of a correct response). The a-parameter is proportion to the slope of the ICF at the point b on the ability scale. The D is a constant in the model, and was introduced by Birnbaum (see [8]) so that the item parameters in the model closely paralleled the item parameters in the normal-ogive model [7], one of the first IRT models that was introduced into the psychometric methods literature in 1952. (This model was quickly dropped when other more tractable models became available.) ‘ n ’ is the number of items in the test. Figure 1 provides an example of an ICF, and highlights the interpretation of the model parameters.

Figure 2 shows the ICFs for five different test items.

From Figure 2, the impact of the item statistics on the shapes of the ICFs can be seen. The statistics for the five items are typical of those observed in

Figure 1 A typical item characteristic function for the three-parameter logistic model (see the S-shaped logistic function)

Figure 2 Five item characteristic functions

Item	b	a	c
1	0.00	1.00	0.20
2	1.00	1.50	0.10
3	-0.50	0.30	0.20
4	-2.00	0.75	0.20
5	1.75	0.50	0.00

practice. An item such as item 2, offers great potential for discriminating among examinees, especially among the more capable examinees. An item such as item 3 adds very little to the psychometric quality of the test because the power of the item to discriminate higher from lower ability is low. Item 5 is only a bit more useful. Sometimes, though, test items like items 3 and 5 are used because they assess content that needs to be covered in a test, and no better items, statistically, are available.

There are important special cases of the three-parameter logistic test model for analyzing dichotomously scored test item data. Setting $c = 0$ in the three-parameter logistic model produces the two-parameter logistic test model, a model that often fits free response items scored 0 or 1, or multiple-choice test items where guessing is minimal such as when the test items are easy. Setting $c = 0$ and $a = 1$, produces the one-parameter logistic model (and better known as the '**Rasch model**'), a model that was developed independently of the three-parameter model by Georg Rasch from Denmark in the late 1950s, and has become very common for the analysis of educational and psychological test data (see, for example, [2]).

Until about 15 years ago, most of the work with item response modeling of data was limited to models

that could be applied to dichotomously scored data – the one-, two-, and three-parameter logistic and normal-ogive models [4]. Even when the data were not dichotomous, it was common to recode the data to reduce it to a binary variable (e.g., with a five point scale, perhaps 0 to 2 would be recoded as 0, and 3 to 4 recoded as 1). This was an unfortunate loss of valuable information when estimating examinee ability.

Many nationally normed achievement tests (e.g., California Achievement Tests, Metropolitan Achievement Tests), university admissions tests (e.g., Scholastic Assessment Test, the Graduate Management Admissions Test, and the Graduate Record Exam) and many state proficiency tests and credentialing exams in the United States consist of multiple-choice tests that are scored 0–1. The logistic test models are typically used with these tests in calibrating test items, selecting items, equating scores across forms, and more.

Today, more use is being made of test data arising from new item types that use polytomous-scoring (i.e., item level data that are scored in more than two categories) such as rating scales for recording attitudes and values, and the scoring of writing samples and complex performance tasks (*see Computer-based Test Designs*, and [14]). Numerous IRT models are available today for analyzing polytomous response data. Some of these models were available in the late 1960s (see Samejima's chapter in [12]) but were either too complex to apply, were not sufficiently well developed (for example, parameter estimation was problematic), or software for applying the models was simply not available. These polytomous IRT response models are especially important in the education and psychology fields because more of the test data today is being generated from tasks that are being scored using multicategory scoring rubrics. Polytomous IRT models like the partial credit model, generalized partial credit model, nominal response model, and the graded response model can handle, in principle, an unlimited number of score categories, and these models have all the same features as the logistic test models introduced earlier (*see Item Response Theory (IRT) Models for Polytomous Response Data*).

The test characteristic function (TCF) given below,

$$E(X) = TCF(\theta) = \sum_{i=1}^n P_i(\theta), \quad (2)$$

provides an important link between true scores in CTT and ability scores in IRT. This relation is useful in explaining how examinees can score well on easy tests and less well on hard tests; and is definitely useful in test design because it provides a basis for predicting test score distributions, or mapping performance standards that are often set on the test score scale to the ability scale.

Trait scores, or ability scores, as they are commonly called, are often scaled to a mean of zero and a standard deviation of one for convenience, and without loss of generality. A normal distribution of ability is neither desired nor expected, nor are scores typically transformed to obtain such distribution. Before scores are reported to examinees, it is common to apply a linear transformation to the ability scores (scaled, 0,1) to place them on a more convenient scale (for example, a scale with mean = 100, SD = 10) that does not contain negative numbers and decimals. It is the test developer's responsibilities to conduct validity investigations to determine exactly what a test, and hence, the ability scores, are measuring.

IRT models are based on strong assumptions about the data: In the case of the logistic test models introduced earlier for analyzing dichotomously scored data, they are (a) the assumption of test unidimensionality and (b) the assumption that the ICFs match or fit the actual data [4]. Other models specify different assumptions about the data (see, for example, [12]). Failure to satisfy model assumptions can lead to problems – for example, expected item and ability parameter invariance may not be present, and using ICFs to build tests, when these functions do not match the actual data, will result in tests that will function differently in practice than expected. These two assumptions will be explored in more detail in the next section.

The primary advantage of IRT models is that the parameters of these models are 'invariant'. This means that examinee ability remains constant over various samples of test items from the domain of content measuring the ability of interest. The accuracy of the estimates may vary (e.g., giving easy items to high ability candidates results in more error in the estimates, than giving items that are more closely matched to the examinee's ability level) but the examinee ability parameter being estimated with each sample is the same. This is known as 'ability parameter invariance'. This is accomplished by considering item statistics along with examinee response

data in the ability estimation process. The property of ability parameter invariance, makes it possible, for example, to compare examinees, even though the tests they have taken may differ considerably in test difficulty.

In the case of item parameter invariance, item parameters are independent of the particular choice of examinee samples. This means that for examinees at a particular point on the ability scale, the probability of a correct response is the same, regardless of the subpopulation from which the examinees are sampled [4]. The item parameters, though not the estimates, are 'examinee sample invariant' and this property is achieved by taking into account the characteristics of the sample of examinees in the item parameter estimation process. This is an immensely useful feature in estimating item statistics because the test developer is freed more or less of the concern about the nature of the examinee sample in item calibration work. Good estimation of these ICFs still requires appropriately chosen samples (large enough to produce stable parameter estimates, and broad enough that these ICFs can be properly estimated – recall that they are nonlinear regression functions), but to a great degree the role that the ability levels of the examinee sample plays can be addressed in the calibration process, and what is produced are estimates of the item parameters that are more or less independent of the examinee samples.

IRT Model Parameter Estimation, Model Fit, and Available Software

Several methods are available for estimating IRT model parameters (see, for example, [4, 7]) including new Bayesian (*see Bayesian Item Response Theory Estimation*), and Monte-Carlo Markov-Chain (*see Markov Chain Monte Carlo Item Response Theory Estimation*) procedures (see, [12]). All of these methods capitalize on the principle of local independence, which basically states that a single dominant factor or ability influences item performance, and is expressed mathematically as

$$P(U_1, U_2, \dots, U_n | \theta) = P(U_1 | \theta) P(U_2 | \theta) \dots P(U_n | \theta) \\ = \prod_{i=1}^n P(U_i | \theta). \quad (3)$$

Here, $U_1, U_2, \dots, U_n$ are the binary scored responses to the items, and n is the total number

of items in the test. In other words, the principle or assumption of local independence, which is a characteristic of all of the popular IRT models, and follows from the assumption of unidimensionality of the test, states that the probability of any particular examinee response vector (of item scores) is given by the product of the separate probabilities associated with those item scores. This means that an examinee's item responses are assumed to be independent of one another, and driven by the examinee's (unknown) ability level. If the item parameters are known, or assumed to be known, the only unknown in the expression is the examinee's ability, and so it is straightforward to solve the equation with one unknown, examinee ability. With maximum likelihood estimation, the value for θ that makes the likelihood of the data that was observed is found (logs of both sides of the equation are taken, the expression for the first derivative with respect to θ is found, and then that expression is set to zero, and the value of θ that solves the differential equation is used as the ability estimate). By working with second derivatives of the likelihood expression, a standard error associated with the ability estimate can be found. For each examinee, item response data is inserted and the resulting equation is solved to find an estimate of θ .

Normally, item parameter estimates are treated as known once they are obtained and placed in an item bank. At the beginning of a testing program, neither item parameters nor abilities are known and then a joint estimation process is used to obtain **maximum likelihood** item parameter estimates and ability estimates (see, [7], for example). Today, more complex estimation procedures are becoming popular and new software is emerging.

Several software packages are available for parameter estimation: BILOG-MG (www.ssicentral.com) can be used with the one-, two-, and three parameter logistic models; and BIGSTEPS (www.winsteps.com), CONQUEST (www.assess.com), LPCN-WIN (www.assess.com), and several other software programs can be used with the Rasch model. The websites provide substantial details about the software.

The assumption of test unidimensionality is that the items in the test are measuring a single dominant trait. In practice, most tests are measuring more than a single trait, but good model fit requires only a

reasonably good approximation to the unidimensionality assumption. One check on unidimensionality that sometimes is applied is this: From a consideration of the items in the test, would it be meaningful to report a single score for examinees? Is there a factor common to the items such as 'mathematics proficiency' or 'reading dimensionality'. Multidimensionality in a dataset might result from several causes: First, the items in a test may cluster into distinct groups of topics that do not correlate highly with each other. Second, the use of multiple item formats (e.g., multiple-choice questions, checklists, rating scales, open-ended questions) may lead to distinct 'method of assessment' factors. Third, multidimensionality might result from dependencies in the data. For example, if responses to one item are conditional on responses to others, multidimensionality is introduced. (Sometimes this type of dimensionality can be eliminated by scoring the set of related items as if it were a 'testlet' or 'super item'.)

Many methods are available to explore the dimensionality of item response data (see [4, 5]). Various reviews of several older methods have found them all in one way or another to have shortcomings. While this point may be discouraging, methods are available that will allow the researcher to draw defensible conclusions regarding unidimensionality. For example, linear factor analysis (e.g., **principal components analysis**), nonlinear factor analysis, and **multidimensional scaling** may be used for this purpose, though not without some problems at the interpretation stage. Further, it is recognized that few constructs are reducible to a strictly unidimensional form and that demonstration of a dominant single trait may be all that is reasonable. For example, using principal components analysis we would expect a dominant first factor to account for roughly 20% or more of the variance in addition to being several times larger than the second factor. Were these conditions met, the assumption of unidimensionality holds to a reasonable degree.

Descriptions of Four IRT Applications

Very brief introductions to four popular applications of IRT follow. Books by Bartram and Hambleton [1], Hambleton, Swaminathan, and Rogers [4], Mills, et al. [9], van der Linden and Glas [11], and Wainer [13] provide many more details on the applications.

Developing Tests

Two of the special features of IRT modeling are item and test information functions. For each item, a test item information function is available indicating where on the reporting scale an item is useful in estimating ability and how much it contributes to an increase in measurement precision. The expression for the item information function (see, [7]) is

$$I_i(\theta) = \frac{[P'_i(\theta)]^2}{P_i(\theta)[1 - P_i(\theta)]}. \quad (4)$$

Figure 3 provides the item information functions corresponding to the items shown in Figure 2 and identified earlier in the entry. Basically, items provide the most measurement information around their ‘b-value’ or level of difficulty and the amount of information depends on item discriminating power. It is clear from Figure 3 that items 2, 1, and 4 are the most informative, though at different places on the ability continuum. This is an important point, because it highlights that were interest in ability estimation focused at, say, the lower end of the continuum (perhaps the purpose of the test is to identify low performing examinees for a special education program), item 4 would be a considerably more useful item than items 1 and 2 for precisely estimating examinee abilities in the region of special interest on the ability scale. Items 3 and 5 provide very little information at any place on the ability continuum.

Figure 3 Five item information functions, corresponding to the ICFs reported in Figure 2

The location of maximum information provided by an item is given by the expression:

$$\theta_{i_{\max}} = b_i + \frac{1}{Da_i} \ln \left[0.5(1 + \sqrt{1 + 8c_i}) \right] \quad (5)$$

With the one- and two-parameter logistic models, the point of maximum information is easily seen to be b_i . With $c = 0.0$, the second term simply drops out of the expression.

The test information function (which is a simple sum of the information functions for items in a test) provides an overall impression of how much information a test is providing across the reporting scale:

$$I(\theta) = \sum_{i=1}^n I_i(\theta) \quad (6)$$

The more information a test provides at a point on the reporting scale, the smaller the measurement error will be. In fact, the standard error of measurement at a point on the reporting scale (called the *conditional standard error of measurement* or simply *conditional standard error*) is inversely related to the square root of the test information at that point:

$$SE(\theta) = \frac{1}{\sqrt{I(\theta)}} \quad (7)$$

Thus, a goal in test development is to select items such that the standard errors are of a size that will lead to acceptable levels of ability estimation errors.

A test information function is the result of putting a particular set of items into a test. Figure 4 provides

Figure 4 Test information function and corresponding standard errors based on the five items used in Figures 2 and 3

the test information function for the items shown in Figure 3, and the corresponding conditional error function for the five item test. In practice, the goal is usually to push test information function up to at least 10, which roughly corresponds to a classical reliability estimate of about .90.

Sometimes, rather than the test information function being a result of item selection and a product of the test development process, it is specified as the ‘target’ and then items can be selected to produce the test information function of interest. Item selection often becomes a task of selecting items to meet content specifications, and statistical specifications (as reflected in a ‘target information function’). One of the newest IRT topics (called ‘automated test assembly’) is the development of procedures for allowing test developers to define the test of interest in considerable detail, translate those specifications into mathematical equations, and then with the appropriate software, actually solve the resulting equations, and select test items from a bank of calibrated test items to meet the requirements for the test (see, [10, 11]).

Identifying DIF

The property of item parameter invariance is immensely useful in test development work, but it is not something that can be assumed with IRT models. The property must be demonstrated across subpopulations of the population for whom the test is intended. This might be male and females; Blacks, Whites, and Hispanics; well-educated and less well-educated examinees; older, middle age, and younger respondents; etc. (see **Differential Item Functioning**) Basically, IRT DIF analyses involve comparing the item characteristic functions obtained in these subpopulations. Much of the research has investigated different ways to summarize the differences between these ICFs (see, [4, 6]). DIF via IRT modeling is not especially easy to implement (because of the number of steps involved in getting the ICFs from two or more groups on a common scale), but the easy graphing capabilities of ICFs makes DIF interpretation more understandable to many practitioners than the use of reporting DIF statistics only.

Test Score Linking or Equating

In many practical testing situations, such as achievement testing, it is desirable to have multiple versions

or forms of a test. For example, a test such as the Scholastic Assessment Test would quickly become of limited value if the same test items were used over and over again. Every high school senior would be going to a coaching school or scanning the Internet to get an advanced look at the test items. Items would become known to test takers and passed on to others about to take the test. Test validity would drop to zero very quickly. So, while multiple forms of a test may be a necessity, it is also important that these tests be statistically equivalent so that respondents do not benefit or be placed at a disadvantage because of the form of the test they were administered. Proper test development is invaluable in producing near equivalent tests, but it is no guarantee, and so ‘statistical equating’ is carried out to link comparable scores on pairs of tests. Statistical equating can be carried out with classical or IRT modeling, but it tends to be easier to do with IRT models and with a bit more flexibility. There is some evidence too that IRT equating may produce a better matching of scores at the low and high end of the ability scale (see, for example, [4, 7]).

Computer-Adaptive Testing (CAT)

‘Adapting a test’ to the performance of the examinee as he/she is working through the test has always been viewed as a very good idea because of the potential for shortening the length of tests (see **Computer-based Testing; Computer-Adaptive Testing**). The basic idea is to focus on administering items where the particular answer of the examinee is the most uncertain – that is, items of ‘medium difficulty’ for the examinee. When testing is done at a computer, ability can be estimated after the administration of each item, and then the ability estimate provides a basis for the selection of the next test items. Testing can be discontinued when the level of precision that is desired for ability estimates is achieved. It is not uncommon for the length of testing to be cut in half with CAT. The computer provides the mechanism for ability estimation and item selection. Item response theory provides a measurement framework for estimating abilities and choosing items. The property of ‘ability parameter invariance’ makes it possible to compare examinees to each other or standards that may have been set despite the fact that they almost certainly took collections of items that differed substantially in their ‘difficulty’. Without IRT, CAT

would lose many of its advantages. CAT is one of the important applications of IRT (see [1, 13]).

Future Directions and Challenges

The IRT field is advancing quickly. Nonparametric models have been introduced and open up a new direction for IRT model building. New models that build in a hierarchical structure are being advanced too (see **Hierarchical Item Response Theory Modeling**). Also, model parameter estimation methods are being developed based on Bayesian, marginal maximum likelihood, and Monte-Carlo Markov-Chain methods (see **Markov Chain Monte Carlo Item Response Theory Estimation**). Automated test assembly based on IRT models and optimization procedures will eventually be used in item selection (see [10]). Initiatives on just about every aspect of IRT are underway.

Despite the advances, challenges remain. One challenge arises because of the potential for multidimensional data. All of the popular IRT models are based on the assumption of a single dominant factor underlying performance on the test. It remains to be seen to what extent new tests are multidimensional, how that multidimensionality can be detected, and how it might be handled or modeled when it is present. A second challenge is associated with model fit. IRT models are based on strong assumptions about the data, and when they are not met, advantages of IRT modeling are diminished or lost. At the same time, approaches to addressing model fit, remain to be worked out, especially the extent to which model misfit can be present without destroying the validity of the IRT model application.

Finally, IRT is not a magic wand that can be used to fix all of the mistakes in test development such as (a) the failure to properly define the construct of interest, (b) ambiguous items, and (c) flawed test administrations. At the same time, it has been demonstrated many times over that IRT models, when they fit the data, and when other important features of sound measurement are present, IRT models provide

an excellent basis for developing tests, and providing valid scores for making decisions about individuals and groups.

Item Response Theory (IRT) Models for Polytomous Response Data

In many applications, such as educational testing, attitude surveys, and psychological scales, items are used that can take scores in multiple categories. For example, on a writing test, there could be an essay that is scored on a scale of 0–6. Alternately, on an opinion scale, there could be Likert-type items for which the response is a rating on a scale of strongly agree to strongly disagree. To model these types of item responses, item response theory (IRT) models that take into account these types of responses can be used to analyze the data and provide information regarding the level of latent trait (see **Latent Variable**) of interest that the respondent possesses. There are many IRT models that can be used to model this type of data, and several of the popular models are presented in this section. The models considered are the Graded Response Model, the Rating Scale Model, the Nominal Response Model, the Partial Credit Model, and the Generalized Partial Credit Model (GPCM) (see **Item Response Theory (IRT) Models for Rating Scale Data**).

Notation

To aid in the reading of the different models, some common notation will be used for all models. In all cases, θ will denote the latent variable of interest. The latent variable could be mathematical achievement, or some personality trait like anxiety, achievement motivation, or quality of life. In any case, the same notation will be used. Additionally, the scores of all items considered will be assumed to belong to one of m_i categories, where i indicates the particular item. Each item can have a different number of categories, but in all cases, the number of categories will be denoted m .

Graded Response Model

Samejima introduced the graded response model (GRM) in 1969 [8]. The GRM represents a family of

models that is appropriate to use when dealing with *ordered* categories. Such ordered categories could relate to constructed response items where examinees can receive various levels of scores, such as 0–4 points. The categories in that instance are 0, 1, 2, 3, and 4, and are clearly ordered. Alternately, the categories could be responses to Likert-type items, such as those in attitude surveys, where the response are strongly agree, agree, disagree, and strongly disagree. Again, there is an order inherent in the categories.

The GRM is a generalization of the two-parameter logistic (2PL) model. It uses the 2PL to provide the probability of receiving a certain score *or higher*, given the level of the underlying latent trait. As there are multiple categories to consider for each item, for any given level of θ , there is a probability of obtaining a score of x or higher. That is, the model provides

$$P_{ix}^*(\theta) = P[U_i \geq x|\theta], \quad (1)$$

where U_i is the random variable used to denote the response to an item with m score categories, and x is the specific score category.

Clearly, in the case where the particular score category is 0, the probability of getting a score of zero or higher must be one. That is,

$$P_{i0}^*(\theta) = 1. \quad (2)$$

Similarly, the probability of getting a score of $m_i + 1$ or higher is zero since the largest score is m_i . That is,

$$P_{i(m_i+1)}^*(\theta) = 0. \quad (3)$$

By defining the model in this way, it is possible to obtain the probability of getting a *specific* score, rather than the probability of getting a specific score *or higher*. This is achieved by

$$P_{ix}(\theta) = P_{ix}^*(\theta) - P_{i(x+1)}^*(\theta). \quad (4)$$

As the model is based on 2PL, there is a discrimination parameter involved for each item.

The model is expressed as:

$$P_{ix}^*(\theta) = \frac{e^{Da_i(\theta - b_{ix})}}{1 + e^{Da_i(\theta - b_{ix})}} \quad (5)$$

and a graphical representation of the same four-category item with equal a -parameters in Figure 1.

Figure 1 Score category response functions for the GRM ($a_i = 1.2$, $b_{i1} = -1.0$, $b_{i2} = 0.0$, $b_{i3} = 2.0$)

Considering Figure 1, the discrimination parameter for the item is 1.0. The category parameters are given by -1.0 , 0.0 , and 2.0 . These category parameters represent the point on the ability scale where an examinee has a 50% chance of getting a score of 1 or higher, 2 or higher, 3 or higher, etc. For example, at $\theta = 0.0$, the examinee has a 50% probability of obtaining a score of 2 or higher (that is, a score of 2, 3, 4, or 5). For values of $\theta > 0.0$, the probability of scoring a 2 or higher is greater than 50%.

Rating Scale Model

The Rating Scale model is an extension of the GRM, where, instead of having one location parameter for each category, b_{ix} , there is one location parameter *per item*, b_i , and a separate category parameter for each score category, c_{ix} . As a result, the model is expressed using

$$P_{ix}^*(\theta) = \frac{e^{Da_i(\theta - b_i + c_{ix})}}{1 + e^{Da_i(\theta - b_i + c_{ix})}}, \quad (6)$$

where this expression provides the probability of a person with latent trait level θ , receiving a score of x or higher, as in the case of the GRM. This model is often used for scoring Likert items; however, if the items have different numbers of score categories, the rating scale model is not appropriate and the GRM should be used (Muraki & Bock, 1997).

Partial Credit Model

As the GRM was an extension of the two-parameter logistic model, the Partial Credit Model (PCM), introduced by Masters in 1982 [6], is an extension of the one-parameter logistic model, or **Rasch model**, described elsewhere in this volume. As such, there is no discrimination parameter included in the model. The Rasch model provides the probability of getting a score of 1 *rather than* a score of 0, given some level of θ . In the case of the PCM, the Rasch model is used for each pair of adjacent categories. Thus, given an item with m_i response options, the Rasch model is used for each pair. In a four-category item, therefore, there are three pairs of adjacent score categories: 0 and 1, 1 and 2, and 2 and 3. Therefore, given a pair of adjacent response categories, $x - 1$ and x , they can be considered as '0' and '1', respectively, for the Rasch model. As such, the PCM provides the probability of obtaining a score of x rather than $x - 1$. This is in contrast to Samejima's GRM, which models the probability of getting a score of ' x or higher' for each score category x .

The model contains a person parameter, θ , as well as $m_i - 1$ parameters for each item. The $m_i - 1$ parameters correspond to the decision between adjacent categories. Therefore, there will always be one fewer parameters than categories. This is seen in the dichotomous case as well: there is one parameter for each item. This parameter results from the dichotomous decision between score categories 0 and 1.

The model can be easily seen as an extension of the Rasch model. For a particular person with trait level θ , and for a particular item, the Rasch model provides the probability of a correct response (i.e., a score of 1) as:

$$\begin{aligned} P(u = 1|\theta) &= \frac{P(u = 1|\theta)}{P(u = 1|\theta) + P(u = 0|\theta)} \\ &= \frac{\exp(\theta - b)}{1 + \exp(\theta - b)}. \end{aligned} \quad (7)$$

As noted previously, this model is monotonically increasing; as the value of θ increases, so does the probability of obtaining a score of 1.

The PCM extends this to the case of multiple score categories, and as noted above, considers only two categories at a time. Therefore, the probability of an examinee with a given level of θ getting a score of

x rather than a score of $(x - 1)$ on a particular item i , which has m categories is given by

$$P(u = x|\theta) = \frac{P[u = x|\theta]}{P[u = x|\theta] + P[u = (x - 1)|\theta]} = \frac{\exp(\theta - b_x)}{1 + \exp(\theta - b_x)}. \quad (8)$$

In this case, it is necessary to index the parameter b , as there will be many such parameters; there is one b for each comparison made, that is, $m - 1$. Again, as θ increases, the probability of getting score x rather than score $x - 1$ increases; however, the probability of getting score x does not necessarily continue to increase, as, at some point, a score of $x + 1$ becomes more likely than a score of x . Therefore, the model expressed in this way does not consider any other response options other than x and $x - 1$. It is often more desirable, and common, to consider the probability of getting a score of x , not just getting a score of x rather than a score of $x - 1$. As such, the more common way to write the model is

$$P(u = x|\theta) = \frac{\exp \sum_{k=0}^x (\theta - b_k)}{\sum_{h=0}^{m-1} \exp \sum_{k=0}^h (\theta - b_k)}. \quad (9)$$

In the case of the Rasch model, the b parameter provides the difficulty of the item. It is the location on the theta scale at which a person has a .50 probability of answering the item correctly. In the PCM, it is a little more complex, as there are multiple score categories, and only two are taken into consideration when estimating the b_x parameter. The value of b_x is the point where the probability of receiving score x is equal to the probability of receiving score $x + 1$.

A graphical representation of the score categories is provided in Figure 2 for a four-category item with $b_0 = -1.0$, $b_1 = 0.0$, $b_2 = 2.0$:

The b_x values are labeled on the graph. One interpretation of these 'step' parameters is to consider that to have a greater probability of getting a score of 1 over that of getting a score of 0, a θ -level greater than -1.0 is necessary. Similarly, to have a greater probability of getting a score of 1 over a score of 2, a θ -level of greater than

Figure 2 Score category response functions for the PCM ($b_{i1} = -1.0$, $b_{i2} = 0.0$, $b_{i3} = 2.0$)

0.0 is required, and similarly, for having a greater probability of getting a score of 3 over a score of 2.

It is interesting to note that the b_x values need not be ordered such that $b_1 < b_2 < \dots < b_{m-1}$ because the parameter represents the relative magnitude of only *two* adjacent probabilities. When the ordering changes, the interpretation becomes more complicated and has been the source of considerable discussion among researchers.

The Generalized Partial Credit Model

In many cases, different items on the same test/scale do have different discriminations. In 1992, Muraki generalized the Partial Credit Model by allowing items to have different discrimination parameters [7]. As such, this model can be seen as an extension of the two-parameter logistic model in the same way that the PCM can be viewed as an extension of the one-parameter logistic model, or the Rasch model. In this instance, adjacent score categories are still considered, and the model provides the probability of obtaining a score of x rather than a score of $x - 1$, just as in the case of the PCM. However, this probability is given by a different function, which is the two-parameter logistic function that has been presented earlier:

$$P(u = x|\theta) = \frac{P[u = x|\theta]}{P[u = x|\theta] + P[u = (x-1)|\theta]} = \frac{\exp Da(\theta - b_x)}{1 + \exp Da(\theta - b_x)}, \quad (10)$$

where D is a scaling constant equal to 1.7, to put θ on the same metric as the normal ogive model, and a is the discrimination parameter for the particular item. Clearly, the PCM can be seen as a special case of this model where $D = 1$ and $a = 1$ for all items.

Again, it is more desirable to have an expression for the probability of obtaining a score of x , and not the probability of obtaining a score of x rather than a score of $x - 1$. Thus, the model can be expressed as before with

$$P(u = x|\theta) = \frac{\exp \sum_{k=0}^x Da(\theta - b_k)}{\sum_{h=0}^{m-1} \exp \sum_{k=0}^h Da(\theta - b_k)}. \quad (11)$$

The b_x parameters can be interpreted the same way as in the PCM. The only difference is the effect of the a -parameter on the resulting curves. Figure 3 provides a graphical representation of the same four-category item with $b_0 = -1.0$, $b_1 = 0.0$, $b_2 = 2.0$ and $a = 1.20$.

Figure 3 Score category response functions for the GPCM ($a_i = 1.2$, $b_{i1} = -1.0$, $b_{i2} = 0.0$, $b_{i3} = 2.0$)

Although the GPCM and the GRM are conceptualized differently, the results obtained from using the two models are very similar.

The Nominal Response Model

Bock introduced the nominal response model (NMR) in 1972, which is the most general of the unidimensional polytomous IRT models [1]. In this model, there is no assumption that the categories are ordered in any particular way. That is, a score of '2' is not necessarily smaller than a score of '3'. An example of this type of scoring can be seen in scoring multiple-choice items, where each response is given a particular value. Consider a multiple-choice item with four options: A, B, C, and D. This item can be viewed as a polytomously scored item where each option receives a score. There is then a probability associated with each response option. For any given level of θ , there is a probability that a person chooses option A, B, C, and D. And these probabilities change as the level of θ changes.

The nominal response model provides the probability that a person with latent trait level, θ , obtains a score of x . The model is expressed as:

$$P_{ix}(\theta) = \frac{e^{a_{ix}\theta + c_{ix}}}{\sum_{k=1}^{m_i} e^{a_{ix}\theta + c_{ix}}}. \quad (12)$$

In this case, each score category has its own discrimination parameter, a_{ix} . It is for this reason that the response categories do not retain the strict ordering. The other parameter, the c_{ix} , is an intercept parameter for each score category. An alternate parameterization of the model exists as:

$$P_{ix}(\theta) = \frac{e^{a_{ix}(\theta - b_{ix})}}{\sum_{k=1}^{m_i} e^{a_{ix}(\theta - b_{ix})}}. \quad (13)$$

which is similar in form to the other models presented in this section. The b_{ix} parameter is a location parameter and $b_{ix} = -c_{ix}/a_{ix}$. A graphical representation of a four-category item is presented in Figure 4.

The most popular IRT models used for scoring polytomous models were presented in this entry. These models have been applied in many contexts in the social sciences, especially the GRM and PCM.

Figure 4 Score category response functions for the NRM

They offer flexibility in the assumptions of the scoring: ordered versus nonordered categories and equal versus nonequal discrimination among items, and as such are capable of modeling a variety of data. The reader is directed to studies such as [2–5, 9, 11, 12] for specific examples. For more detail about the models presented here, as well as other IRT models, the reader is referred to [10].

Item Response Theory (IRT) Models for Rating Scale Data

IRT Models for Rating Scale Data

Rating scales are the most common formats for collecting observations in the behavioral and social sciences. Rating scale item i provides the opportunity for a person to select a score X in $m_i + 1$ ordered categories ($x = 0, 1, \dots, m_i$). For example, the person might be an examinee indicating an attitude using a Likert Scale (0 = Strongly Disagree, 1 = Disagree, 2 = Uncertain, 3 = Strongly Agree, 4 = Agree) or a rater judging the quality of student writing (0 = novice, 1 = proficient, 2 = accomplished). If there are two response categories (0 = incorrect, 1 = correct), then the ratings yield dichotomous data (see **Item Response Theory (IRT) Models for Dichotomous Data**). If there are three or more categories, then the ratings yield polytomous data. Higher scores generally indicate a higher location on the construct. In IRT, the construct is defined as an unobservable construct or trait. The goal of measurement is locate both persons and items on this underlying construct in order to define measuring instrument.

One of the central problems in psychometrics is the development of models that connect person measures and item calibrations in a meaningful way to represent a construct. The basic idea that motivates the use of IRT models for rating scale data is that the scoring of $m + 1$ ordered categories with ordered integers (0, 1, $\dots$, m) using the assumption that there are equal intervals between the categories may not be justified. IRT models provide a framework to explicitly examine this assumption, and parameterize the categories without this assumption. Specifically, IRT models for rating scale data are used to model category response functions (CRFs) that link the probability of a specific rating with person measures and a set of characteristics reflecting item and category calibrations. The category response functions (CRFs) represent the probability of obtaining a score of x on item i as a function of a person's location on the construct θ . The CRFs can be written as follows:

$$P_{xi}(\theta) = \text{pr}(X_i = x|\theta), \quad (1)$$

for $x = 0, 1, \dots, m$. The IRT models for rating scale data vary in terms of how they define the operating characteristic functions (OCFs). CRFs and OCFs will be defined for each model in the following sections.

There are several different ways to categorize IRT models for analyzing rating scale data. In this entry, the specific models described are unidimensional models for ordered categories. Following Embretson and Reise [6], these models can be viewed as either direct or indirect models. Direct models focus directly on estimating CRFs, while indirect models require two steps that involve first estimating the OCFs and then the CRFs. Thissen and Steinberg [18] referred to these models as divide-by-total and difference models respectively. They also point out that it is possible to go back and forth between the divide-by-total and difference forms, although the derivational form of the model is usually less complex algebraically.

Direct Models

Partial Credit Model

The Partial Credit Model [PCM; 9, 10] is a unidimensional IRT model for ratings in two or more ordered categories. The PCM is a **Rasch model**, and therefore provides the opportunity to realize a variety of desirable measurement characteristics, such as separability of person and item parameters, sufficient statistics for parameters in the model, and specific objectivity [14]. When good model-data fit is obtained, then the PCM, as well as other Rasch models, yields invariant measurement [7]. The PCM is a straightforward generalization of the Rasch model for dichotomous data [15] applied to pairs of increasing adjacent categories.

The Rasch model for dichotomous data can be written as:

$$\frac{P_{i1}(\theta)}{P_{i0}(\theta) + P_{i1}(\theta)} = \frac{\exp(\theta - \delta_{i1})}{1 + \exp(\theta - \delta_{i1})}, \quad (2)$$

where $P(\theta)_{i1}$ is the probability of scoring 1 on item i , $P(\theta)_{i0}$ is the probability of scoring 0 on item i , θ is the location of the person on the construct, and δ_{i1} is the location on the construct where the probability of responding in adjacent categories, 0 and 1, is equal. For the dichotomous case δ_{i1} is defined as the difficulty of item i . Equation (2) represents the operating characteristics function for the PCM. When

2 IRT Models for Rating Scale Data

the data are collected with more than two response categories, then the OCF can be generalized as

$$\frac{P_{ix}(\theta)}{P_{ix-1}(\theta) + P_{ix}(\theta)} = \frac{\exp(\theta - \delta_{ix})}{1 + \exp(\theta - \delta_{ix})}, \quad (3)$$

where $P(\theta)_{ix}$ is the probability of scoring x on item i , $P(\theta)_{ix-1}$ is the probability of scoring $x - 1$ on item i , θ is the location of the person on the construct, and δ_{ix} is the location on the construct where the probability of responding in adjacent categories, $x - 1$ and 1 , is equal.

The category response function (CRF) for the PCM is:

$$P_{ix}(\theta) = \frac{\exp\left[\sum_{j=0}^x (\theta - \delta_{ij})\right]}{\sum_{r=0}^{mi} \exp\left[\sum_{j=0}^r (\theta - \delta_{ij})\right]}, \quad (4)$$

$x_i = 0, 1, \dots, m_i,$

where $\sum_{j=0}^0 (\theta - \delta_{ij}) \equiv 0$. The δ_{ij} parameter is still interpreted as the intersection between the two consecutive categories where the probabilities of responding in the adjacent categories is equal. The δ_{ij} term is described as a step difficulty by Masters and Wright [10]. Embretson and Reise [6] have suggested calling the δ_{ij} term a category intersection parameter. It is important to recognize that the item parameter δ_{ij} represents the location on the construct where a person has the same probability of responding in categories x and $x - 1$. These conditional probabilities for adjacent categories are expected to increase, but they are not necessarily ordered from low to high on the construct θ . By defining the item parameters locally, it is possible to verify that persons are using the categories as expected. See Andrich [3] for a detailed description of the substantive interpretation of disordered item category parameters.

Generalized Partial Credit Model

Muraki [12, 13] formulated the Generalized Partial Credit Model (GPCM) based on Master's PCM [9]. The GPCM is also a unidimensional IRT model for ratings in two or more ordered categories. One distinguishing feature of the GPCM is the use of the two-parameter IRT model for dichotomous data [4, 8]

as the OCF. As pointed out in the previous section, the OCF for the PCM is the dichotomous Rasch model. Two-parameter IRT model allows for the estimation of two item parameters: item difficulty and item discrimination. These item parameters define location and scale. The OCF for the GPCM is

$$\frac{P_{ix}(\theta)}{P_{ix-1}(\theta) + P_{ix}(\theta)} = \frac{\exp[\alpha_i(\theta - \delta_{ix})]}{1 + \exp[\alpha_i(\theta - \delta_{ix})]}, \quad (5)$$

where $P(\theta)_{ix}$ is the probability of scoring x on item i , $P(\theta)_{ix-1}$ is the probability of scoring $x - 1$ on item i , θ is the location of the person on the construct, δ_{ix} is the location on the construct where the probability of responding in adjacent categories, $x - 1$ and 1 , is equal, and α_i is the item discrimination or slope parameter. The CRF for the GPCM with two or more ordered response categories is

$$P_{ix}(\theta) = \frac{\exp\left[\sum_{j=0}^x \alpha_i(\theta - \delta_{ij})\right]}{\sum_{r=0}^{mi} \exp\left[\sum_{j=0}^r \alpha_i(\theta - \delta_{ij})\right]}, \quad (6)$$

$x_i = 0, 1, \dots, m_i,$

where $\delta_{i0} \equiv 0$. Sometimes a scaling constant of 1.7 is added to the model in order to place the θ scale in the same metric as the normal ogive model. The addition of an item discrimination parameter into the OCFs allows for a scale parameter in the CRFs that reflects category spread. The GPCM provides additional information about the characteristics of rating scale data as compared to the PCM. The addition of the scale parameters means that the GPCM is likely to provide better model-data fit than the PCM. The tradeoff is that it is no longer possible to separate person and item parameters; for example, the raw score is no longer a sufficient statistic for locating persons on the construct.

Rating Scale Model

The Rating Scale Model [RSM; 1, 2] is another unidimensional IRT model that can be used analyze ratings in two or more ordered categories. The RSM, as was the PCM, is a member of the Rasch family of IRT models, and therefore shares the desirable measurement characteristics, such as invariant measurement [7] when there is good model-data fit. The

RSM is similar to the PCM, but the RSM was developed to analyze rating scale data with a common or fixed number of response categories across a set of items designed to measure a unidimensional construct or construct. The PCM does not require the same number of categories for each rating scale item. Likert scales are a prime example of this type of format for rating scales. For items with the same number of response categories, the RSM decomposes the category parameter, δ_{ij} , from the PCM into two parameters: a location parameter λ_i that reflects item difficulty and a category parameter δ_j . In other words, the δ_{ij} parameter in the PCM is decomposed into two components, $\delta_{ij} = (\lambda_i + \delta_j)$ where λ_i are the location of the items on the construct and the δ_j are the category parameters across items. The category parameters are considered equivalent across items for the RSM. The OCFs for the RSM is

$$\frac{P_{ix}(\theta)}{P_{ix-1}(\theta) + P_{ix}(\theta)} = \frac{\exp[\theta - (\lambda_i + \delta_x)]}{1 + \exp[\theta - (\lambda_i + \delta_x)]}, \quad (7)$$

where $P(\theta)_{ix}$ is the probability of scoring x on item i , $P(\theta)_{ix-1}$ is the probability of scoring $x - 1$ on item i , θ is the location of the person on the construct, λ_i are the location of the items on the construct, and δ_x is the location on the construct where the probability of responding in adjacent categories, $x - 1$ and 1 , is equal across items. The δ_x parameter is also called the *centralized threshold*. The CRF for the RSM is

$$P_{ix}(\theta) = \frac{\exp \left[\sum_{j=0}^x (\theta - (\lambda_i + \delta_j)) \right]}{\sum_{r=0}^m \exp \left[\sum_{j=0}^r (\theta - (\lambda_i + \delta_j)) \right]}, \quad (8)$$

$x = 0, 1, \dots, m,$

where $\sum_{j=0}^0 (\theta - (\lambda_i + \delta_j)) \equiv 0$. For the RSM, the shape of the OCFs and CRFs across items are the same, while the location varies. Both the RSM and PCM become the dichotomous Rasch model when the rating scale data are collected with two response categories.

Indirect Models

Graded Response Model

The graded response model [GRM; 16, 17] is another unidimensional IRT model for ordered responses. The GRM is an indirect model [6] that requires first the estimation of the OCFs, and then second the subtraction of the OCFs to obtain the CRFs. Thissen and Steinberg [18] call the GRM a difference model. The OCFs for the GRM are two-parameter IRT models for dichotomous data [4, 8]. Although both the GRM and the GPCM share this form for the OCFs, the GRM dichotomizes the categories within the rating scale in a different way. For example, the GRM treats four ordered response categories as a series of three dichotomies as follows: 0 vs. 1, 2, 3; 0, 1 vs. 2, 3; 0, 1, 2 vs. 3. While the PCM, GPCM, and RSM group adjacent categories to form the dichotomies: 0 vs. 1; 1 vs. 2; 2 vs. 3. This difference influences the substantive interpretations of the category parameters in the models. The OCFs for the GRM are modeling the probability of a person scoring x or greater on item i , while the direct models are modeling the probability of x or $x - 1$ for adjacent categories. The OCF for the GRM is

$$P_{ix}^*(\theta) = \frac{\exp[\alpha_i(\theta - \beta_{ij})]}{1 + \exp[\alpha_i(\theta - \beta_{ij})]}. \quad (9)$$

The β_{ij} parameter is interpreted as the location on the construct necessary to respond above the j threshold on item i with a probability of .50, θ is the location of a person on the construct, and α_i is the slope parameter common across OCFs within item i . The slope parameter is constrained to be equal within item i , and this is called the *homogeneous case of the GRM*. The CRF for the GRM is

$$P_{ix}(\theta) = \frac{\exp[\alpha_i(\theta - \beta_{ix})]}{1 + \exp[\alpha_i(\theta - \beta_{ix})]} - \frac{\exp[\alpha_i(\theta - \beta_{i(x+1)})]}{1 + \exp[\alpha_i(\theta - \beta_{i(x+1)})]}, \quad (10)$$

$x_i = 1, \dots, m_i,$

or

$$P_{ix}(\theta) = P_{ix}^*(\theta) - P_{i(x+1)}^*(\theta), \quad (11)$$

where $P_{i(x=0)}^*(\theta) = 1.0$ and $P_{i(x=mi+1)}^*(\theta) = 0.0$. It is important to highlight the substantive interpretations of category parameters β_{ij} of the GRM. The

4 IRT Models for Rating Scale Data

β_{ij} is not the location on the construct where a person has the same probability of being in adjacent categories – this category parameter is not the point of intersection. The category parameters in the PCM, GPCM, and RSM do represent the intersection points. The category parameters β_{ij} are parameterized to be ordered within an item: $\beta_{i1} \leq \beta_{i2} \dots \leq \beta_{im}$. The GRM has a historical connection to the earlier work of **Thurstone** on the method of successive intervals [5] with the important distinction that a person parameter is added to the GRM model. The β_{ij} parameters are sometimes called *Thurstone thresholds*. These Thurstone thresholds represent the location on the construct where the probability of being rated j or above equals the

probability of being in the categories below j for item i .

Modified Graded Response Model

Muraki [11] proposed a Modified Graded Response Model (MGRM) as a restricted version of the GRM [16]. The MGRM is designed for rating scale data that has a fixed number of common response formats across items. The MGRM is unidimensional IRT model for ordered response data. As with the GRM, the MGRM is an indirect model that requires a two-step process with separate estimation of the OCFs, and then the creation of the CRFs through subtraction. The MGRM is analogous to Thurstone's

Figure 1 Partial credit model

method of successive intervals or categories [6]. The distinctive feature of the MGRM is the reparameterization of the GRM category parameter β_{ij} into two components: a location parameter β_i and a category threshold parameter τ_j that is common across items: $\beta_{ij} = (\beta_i + \tau_j)$. The OCF for the MGRM is

$$P_{ix}^*(\theta) = \frac{\exp[\alpha_i(\theta - \beta_i + \tau_j)]}{1 + \exp[\alpha_i(\theta - \beta_i + \tau_j)]} \quad (12)$$

and the CRF is

$$P_{ix}(\theta) = \frac{\exp[\alpha_i(\theta - \beta_i + \tau_j)]}{1 + \exp[\alpha_i(\theta - \beta_i + \tau_j)]}$$

$$- \frac{\exp[\alpha_i(\theta - \beta_i + \tau_{(j-1)})]}{1 + \exp[\alpha_i(\theta - \beta_i + \tau_{(j-1)})]},$$

$$x = 1, 2, \dots, m, \quad (13)$$

or

$$P_{ix}(\theta) = P_{ix}^*(\theta) - P_{i(x+1)}^*(\theta), \quad (14)$$

where $P_{i(x=0)}^*(\theta) = 1.0$ and $P_{i(x=mi+1)}^*(\theta) = 0.0$.

Graphical Displays of the Five Models

Figures 1 to 5 provide a graphical framework for comparing some of the essential features of the

Figure 2 Generalized partial credit model

6 IRT Models for Rating Scale Data

Figure 3 Rating scale model

five IRT models for rating scale data described in this entry. Panels A to F in each figure illustrate the OCFs and CRFs for the five models. The left columns present the OCFs and the right columns present the CRFs. Panels A and B show the OCF and CRF for the dichotomous case, while Panels C through F illustrate these functions for the polytomous case (three ratings) with various values of the parameters for each model. In each figure, the x -axis is the theta value (θ) that represents the location of persons on the latent variable or construct. The y -axis is the conditional probability of

responding in a particular category as a function of the category parameters and the θ location of each person.

Figures 1 to 3 present the direct models (PCM, GPCM, RSM), while Figures 4 and 5 illustrate the indirect models (GRM, MGRM). It is beyond the scope of this entry to provide an extensive comparative discussion of the models, but several points should be noted. First, starting with the PCM in Figure 1, it is easy to see that as the category parameters δ_{ix} become closer together (comparing Panels D and F) the probability of being in

Figure 4 Graded response model

the middle category decreases and the CRFs suggest that less information is being conveyed in this case. Second, Figure 2 for the GPCM illustrates how the addition of a slope or scale parameter, α_i , influences the shape or spread of the OCFs and CRFs. Comparing Panel D in Figure 1 (PCM) with Panels D and F in Figure 2 (GPCM) clearly shows how values of α_i greater than 1 ($\alpha_1 = 1.5$) lead to more peaked CRFs (Figure 2, Panel D), while values of α_i less than 1 ($\alpha_1 = 0.5$) lead to flatter CRFs (Figure 2, Panel F). Third, the RSM shown in Figure 3 illustrates the assumption that even though item locations can change ($\lambda_1 = 0, \lambda_2 = 1$), the rating structure is modeled

to constant across items ($\delta_{11} = \delta_{12} = -0.5, \delta_{21} = \delta_{22} = 0.5$). This is shown in Panels C to F in Figure 3 (RSM).

Figures 4 and 5 present the indirect models (GRM and MGRM). It is important to note that even though the dichotomous cases (Panels A and B) appear graphically equivalent to the direct models in Figures 1 to 3, the substantive definitions and underlying models are distinct. The category parameters for item i , β_{ij} , for the GRM represents the location on the construct where being rated x or above equals the probability of being in the categories below x for item i , while the category parameters for the direct models (PCM, GPCM, and RSM) represent

Figure 5 Modified graded response model

the intersections between CRFs. The GRM presented in Figure 4 illustrates how the scale parameter, α_i , influences the shape (flatness or peakedness) of the CRFs as it does for the direct models. Values of α_i greater than 1 ($\alpha_1 = 1.5$) lead to more peaked CRFs (Figure 4, Panel D), while values of α_i less than 1 ($\alpha_1 = 0.5$) lead to flatter CRFs (Figure 4, Panel F). The MGRM shown in Figure 5 models the rating structure ($\beta_{ij} = \beta_i + \tau_j$) as constant across items. The MGRM shown in Figure 5 illustrates the assumption that even though item location can change ($\beta_1 = 0.0, \beta_2 = 1.0$), the rating structure is modeled to constant across items ($\tau_{11} = \tau_{12} = -1.0, \tau_{21} = \tau_{22} = 1.0$). This is shown in Panels C to F in Figure 5 (MGRM).

Summary

This entry provides a very brief introduction to several IRT models for rating scale data. Embretson and Reise [6] and van der Linden and Hambleton [19] should be consulted for detailed descriptions of these models, as well as descriptions of additional models not included in this entry. The development, comparison, and refinement of IRT models for rating scale data is one of the most active areas in psychometrics.

Jackknife

The jackknife is a resampling procedure that is parallel to several other resampling methods, including the **bootstrap**, the **randomization test**, and **cross-validation**. These methods are designed to generate an empirical **sampling distribution**, which can be used to do hypothesis testing, to estimate standard errors, and to define **confidence intervals**. They have particular value in statistical settings in which the assumptions of parametric statistical procedures are not appropriate. These methods are alternatives to the whole class of hundreds of parametric statistical procedures, including t Tests, the **analysis of variance (ANOVA)**, regression (see **Multiple Linear Regression**), and so on.

Parametric procedures such as the t Test and ANOVA (developed by **Fisher**, **Gosset**, and others in the early twentieth century), were based on theoretical sampling distributions. The mathematical development of these distributions was, at least in part, a necessary response to the computational limitations of the time, which precluded using computationally intensive methods involving resampling. In fact, Fisher invented the first resampling procedure, the randomization test, but could not use it extensively because of computational limitations [3]. He was convinced enough of the value of resampling methods to note that ‘the statistician does not carry out this very tedious process but his conclusions have no justification beyond the fact that they could have been arrived at by this very elementary method (quoted in Edgington [1]).’ Edgington characterized resampling methods as ‘the substitution of computational power for theoretical analysis’ (p. 3). Efron [2] noted that ‘From a traditional point of view, [resampling] methods . . . are prodigious computational spendthrifts. We blithely ask the reader to consider techniques which require the usual statistical calculations to be multiplied a thousand times over. None of this would have been feasible twenty-five years ago, before the era of cheap and fast computation (p. 2)’.

Even with the development of the computer, and the almost unlimited computational availability of the modern computing era, the use of resampling procedures in applied research was slow to develop (see

discussion in [1]). By the beginning of the twenty-first century, however, there are many software systems that support and implement resampling methods (see [7] for a discussion of these programs). Further, the use of resampling methods is becoming more integrated into applied statistics and research settings.

The jackknife was originally developed by Quenouille [6] and **Tukey** [8]. Tukey named it the ‘jackknife’ to ‘suggest the broad usefulness of a technique as a substitute for specialized tools that may not be available, just as the Boy Scout’s trusty tool serves so variedly [5].’ Mosteller and Tukey follow with a more specific description: ‘The jackknife offers ways to set sensible confidence limits in complex situations (p. 133)’. Efron [2], the developer of the bootstrap, named the jackknife method after its developers, the ‘Quenouille–Tukey jackknife’.

In fact, the jackknife can be considered a whole set of procedures, because the original development has been expanded, and new versions of the jackknife have been proposed. For example, Efron [2] discusses the ‘infinitesimal jackknife,’ which provides an alternative to the traditional jackknifed standard deviation. Efron refers the reader to several highly technical articles for sophisticated treatment of the jackknife, including its asymptotic theory (e.g., [4]).

How is the jackknife applied? According to Mosteller and Tukey [5, p. 133], ‘The basic idea is to assess the effect of each of the groups into which the data have been divided . . . through the effect upon the body of data that results from *omitting* that group.’ However, the use of the method has been reformulated since that description. In particular, instead of viewing the effect of ‘omitting that group,’ as suggested in Tukey’s work, a more modern view is to consider resampling without replacement to create a subsample of the original data (which is practically equivalent to Tukey’s conceptualization, but allows more conceptual breadth).

Rodgers [7] defined a taxonomy that organizes the various resampling methods in relation to two conceptual dimensions relevant to defining the empirical sampling distribution – resampling with or without replacement, and resampling to re-create the complete original sample or resampling to create a subsample. The jackknife method involves repeatedly drawing samples without replacement that are smaller than the original sample (whereas, for example, the bootstrap involves resampling with replacement to re-create the complete sample, and the randomization test involves

resampling without replacement to re-create the complete sample).

Mosteller and Tukey [5] provided four different examples of how the jackknife can be used, and a description of their examples is instructive. The first example (p. 139) used the jackknife to compute a confidence interval for a standard deviation obtained from 11 scores that were highly skewed. The second example (p. 142) applied the jackknife to estimate the 10% point in a whole population of measurements when the data were five repeated measures from 11 different individuals. The third example (p. 145) applied the jackknife to the log transforms of a sample of the populations of 43 large US cities for two purposes, to reduce bias in estimating the average size, and to compute the standard error of this estimate. Finally, the fourth example, a more complex application of the jackknife, obtained jackknifed estimators of the stability of a discriminant function (see **Discriminant Analysis**) defined to distinguish which of the *Federalist* papers were written by Hamilton and which ones by Madison.

As a more pragmatic and detailed example, consider a research design with random assignment of 10 subjects to a treatment or a control group ($n = 5$ per group). Did the treatment result in a reliable increase? Under the null hypothesis of no group difference, the 10 scores are sorted into one or the other group purely by chance. The usual formal evaluation of the null hypothesis involves computation of a two-independent-group t -statistic, which is a scaled version of a standardized mean difference between the two groups. This measure is compared to the distribution under the null hypothesis that is modeled by the theoretical t distribution. The validity of this statistical test rests on a number of parametric statistical assumptions, including normality and independence of errors, and homogeneity of variance. As an alternative that rests on fewer assumptions, the null distribution can be defined as an empirical t distribution using a jackknife or other resampling procedure.

To illustrate the use of the jackknife in this problem, we might decide to delete one observation from each group, and build an empirical sampling distribution from the many t statistics that would be obtained. One such null sampling model would involve sampling without replacement from the original ten observations until each group has four observations. There are $10!/[4! \times 4! \times 2!] = 3150$ different resamples that can be formed in this way. The

t -statistic is computed in each of these 3150 resampled datasets, providing a null sampling distribution for the t -statistic. (Alternatively, a random sample of these 3150 resampled datasets could be used to approximate this distribution [1]). If these 3150 t statistics are ordered, the position of the one that was actually observed in the sample can be found and an empirical P value computed by observing how extreme the actually observed t -value is in relation to this empirical null distribution. This P value – equivalent conceptually to the P value obtained from the appropriate parametric test, a two-independent group t Test – can be used to draw a statistical conclusion about group differences. Appropriately-chosen **quantiles** of the empirical t distribution can be used together with a jackknife estimate of the standard error of the mean difference to estimate the bounds of a confidence interval for the mean difference.

An example of a jackknife in a correlation and regression setting – one that follows exactly from Quenouille's original development of the jackknife – is presented in Efron [2, p. 9]. There, he uses the jackknife to estimate bias in the sample correlation between 1973 LSAT and GPAs of entering law school students.

How would a researcher decide when to use the jackknife, instead of one of the alternative resampling schemes, or the equivalent parametric procedure? There are several considerations, but no single definitive answer to this question. First, in some cases, the appropriate sampling model (e.g., resampling with or without replacement) is dictated by the nature of the problem. Settings in which the natural sampling model appears to involve sampling without replacement would naturally lead to the jackknife or the randomization test. Second, when the assumptions of parametric tests are met, there are both practical and statistical advantages to using those; when they are clearly and strongly violated, there are obvious advantages to the resampling methods. Third, the history and background of the jackknife originated from problems in the estimation and evaluation of bias; Efron [2, Chapter 2] gives a careful treatment of this focus. Finally, there are statistical reasons to prefer the bootstrap over the other resampling procedures in general hypothesis testing settings. Although the jackknife works well in such settings, the bootstrap will often outperform the jackknife.

Jonckheere–Terpstra Test

The m treatment levels must be ordered prior to any examination of the data. Assume independent random samples of response to treatment having sizes $n_1, n_2, \dots, n_m$ for the m ordered treatment levels. Let $x_{u,j}$ indicate the treatment response of the j th case receiving treatment level u .

For each of the $M = m(m-1)/2$ possible pairs of treatment levels, $u < v$, compute the quantity

$$J(u, v) = \sum_{j=1, \dots, n_u} \sum_{k=1, \dots, n_v} c(x_{u,j}, x_{v,k}), \quad (1)$$

where $c(x_{u,j}, x_{v,k})$ is 1, $1/2$, or 0, depending on whether $x_{u,j}$ is less than, equal to, or greater than $x_{v,k}$.

$J(u, v)$ will take its minimum value of 0 if every response at treatment level v is smaller than the smallest response at level u . It will take its maximum value of $(n_u \times n_v)$ if every response at treatment level v is greater than the largest response at level u . Larger values of $J(u, v)$ are consistent with response magnitude increasing between treatment levels u and v .

The Jonckheere–Terpstra test statistic [2] is the sum of the $J(u, v)$ terms over the M distinct pairs of treatment levels:

$$J = \sum_{u=1, (m-1)} \sum_{v=u, m} J(u, v). \quad (2)$$

Large values of J favor the alternative hypothesis.

Under the null hypothesis, the treatment responses are exchangeable among the treatment levels. Thus, the Jonckheere–Terpstra test is a permutation test (see **Permutation Based Inference**) – its null reference distribution consists of the values of J for all possible permutations of the $N = n_1 + n_2 + \dots + n_m$ responses among the m treatments, preserving the treatment level group sizes. For larger sample sizes, a Monte Carlo (see **Monte Carlo Simulation**) approximation to the null reference

distribution can be produced by randomly sampling a very large number of the possible permutations, for example, 5000. This test is available in the XactStat (www.cytel.com) and SC (www.mole-soft.demon.co.uk) packages.

For a range of small sample sizes, tables of critical values of J are provided in [1]. These are strictly valid only in the absence of ties. An asymptotic approximation for large sample sizes is also described in [1].

Example

The data in the table below are taken from [3]. A sample of 30 student volunteers were taught a finger-tapping task and then randomized to one of three treatments. They received a drink containing 0 mg caffeine, 100 mg caffeine, or 200 mg caffeine and were then retested on the finger-tapping task. The substantive hypothesis was that increased dosages of caffeine would be accompanied by increased tapping speeds (Table 1).

The jonckex function in SC package reports a value of J of 229.5. The P value for the exact (permutation) test was 0.0008, and for the large-sample normal approximation the value was 0.0011. Tapping speed clearly increases with caffeine consumption.

Kendall, Maurice George

Born: September 6, 1907, in Northamptonshire, UK.

Died: March 29, 1983, in Surrey, UK.

At his first secondary school, Derby Central School, Kendall was initially more interested in languages than in mathematics. But near the end of his secondary schooling his mathematical aptitude began to appear, and the improvement was so great that he was awarded a scholarship to study at St John's College, Cambridge, where he graduated as a mathematics Wrangler in 1929. From Cambridge, Kendall entered and passed the examinations to enter the administrative class of the Civil Service and joined the Ministry of Agriculture and Fisheries. It was here that Kendall first became involved in statistical work.

It was in 1935 that Kendall, while spending part of his holiday reading statistics books at the St John's College library, met **G. Udny Yule** for the first time. The result of this meeting was eventually the recruitment of Kendall by Yule to be joint author of a new edition of *An Introduction to the Theory of Statistics*, first published in 1911, and appearing in its 14th edition in the 1950s [6].

The work with Yule clearly whetted Kendall's appetite for mathematical statistics and he attended lectures at University College, London and began publishing papers on statistical topics. Early during World War II, Kendall left the Civil Service to take up the post of statistician to the British Chamber of Shipping, and despite the obvious pressures of such a war time post, Kendall managed, virtually single-handedly, to produce Volume One of *The Advanced Theory of Statistics* in 1943 and Volume Two in 1946. For the next 50 years, this text remained the standard work for generations of students of mathematical statistics and their lecturers and professors.

In 1949, Kendall moved into academia, becoming Professor of Statistics at the London School of Economics where he remained until 1961. During this time, he published a stream of high-quality papers on a variety of topics including the theory of

k-statistics, **time series** and rank correlation methods (*see* **Rank Based Inference**). His monograph on the latter remains in print in the twenty-first century [2]. Kendall also helped organize a number of large sample survey projects in collaboration with governmental and commercial agencies. Later in his career, Kendall became Managing Director and Chairman of the computer consultancy, SCI-CON. In the 1960s, he completed the rewriting of his major book into three volumes, which was published in 1966 [1]. In 1972, he became Director of the World Fertility Survey. Kendall was awarded the Royal Statistical Society's Guy Medal in Gold and in 1974 a knighthood for his services to the theory of statistics. Other honors bestowed on him include the presidencies of the Royal Statistical Society, the Operational Research Society, and the Market Research Society.

Sixty years on from the publication of the first edition of *The Advanced Theory of Statistics* the material of the book remains (although in a somewhat altered format [3–5]) the single most important source of basic information for students of and researchers in mathematical statistics. The book has remained in print for as long as it has, largely because of Kendall's immaculate organization of its contents, and the quality and style of his writing.

Kendall's Coefficient of Concordance

Kendall's Coefficient of Concordance, W , is a measure of the agreement between several judges who have rank ordered a set of entities. In this sense, it is similar to an **intraclass correlation** for ranked data.

As an illustration, we use the same example as for intraclass correlation (from [1]) in which lecturers were asked to mark eight different essays on a percentage scale. Imagine, however, that the lecturers had rank ordered the essays (assigning a rank of 1 to the best and a rank of 8 to the worst) as in Table 1.

If the lecturers agree, then the total ranks for each essay will vary. For example, if all four lecturers thought essay 6 was the best, then the sum of ranks would be only 4, and if they thought essay 3 was the worst, then it would have a total rank of $8 \times 4 = 32$. However, if there is a lot of disagreement then particular essays will have both high and low ranks assigned to them and the resulting totals will be roughly equal. In fact, if there is maximal disagreement between judges, the totals for each essay will be the same.

Kendall's statistic represents the ratio of the observed variance of the total ranks of the ranked entities to the maximum possible variance of the total ranks. In this example, it would be the variance of total ranks for the essays divided by the maximum possible variance in total ranks of the essays. The first step is, therefore, to calculate the variance of total ranks for essays. To estimate this variance, we use a sum of squared error. In general terms, this is the squared difference between an observation and

the mean of all observations:

$$ss = \sum_{i=1}^n (x_i - \bar{x})^2. \quad (1)$$

The mean of the total ranks for each essay can be calculated in the usual way, but it is also equivalent to $k(n+1)/2$ in which k is the number of judges and n is the number of things being ranked.

This gives us:

$$\begin{aligned} SS_{\text{Rank Totals}} &= (19 - 18)^2 + (15 - 18)^2 + (25 - 18)^2 \\ &\quad + (21 - 18)^2 + (21 - 18)^2 + (14 - 18)^2 \\ &\quad + (17 - 18)^2 + (12 - 18)^2 \\ &= 170. \end{aligned} \quad (2)$$

This value is then divided by an estimate of the total possible variance. We could get this value by simply working out the sum of squared errors for row totals when all raters agree. In this case, the row totals would be 4 (all agree on a rank of 1), 8 (all agree a rank of 2), 12, 16, 20, 24, 28, 32 (all agree a rank of 8). The resulting sum of squares would be:

$$\begin{aligned} SS_{\text{Max}} &= (4 - 18)^2 + (8 - 18)^2 + (12 - 18)^2 \\ &\quad + (16 - 18)^2 + (20 - 18)^2 + (24 - 18)^2 \\ &\quad + (28 - 18)^2 + (32 - 18)^2 \\ &= 672. \end{aligned} \quad (3)$$

The resulting coefficient would be:

$$W = \frac{SS_{\text{Rank Totals}}}{SS_{\text{Max}}} = \frac{170}{672} = 0.25. \quad (4)$$

I have done this just to show what the coefficient represents. However, it is a rather cumbersome method because of the need to calculate the maximum possible sums of squares. Thanks to some clever mathematics, we can avoid calculating the maximum possible sums of squares in this long-winded way and simply use the following equation:

$$W = \frac{12 \times SS_{\text{Rank Totals}}}{k^2, (n^3 - n)}, \quad (5)$$

where k is the number of judges and n is the number of things being judged. We would obtain the same answer:

$$W = \frac{12 \times 170}{16(512 - 8)} = \frac{2040}{8064} = 0.25. \quad (6)$$

Table 1 Eight essays ranked by four lecturers

Essay	Dr. Field	Dr. Smith	Dr. Scrote	Dr. Death	Total
1	7	7	3	2	19
2	6	6	2	1	15
3	8	8	6	3	25
4	5	5	7	4	21
5	4	4	8	5	21
6	1	3	4	6	14
7	3	2	5	7	17
8	2	1	1	8	12
					Mean = 18

2 Kendall's Coefficient of Concordance

A significance test can be carried out using a chi-square statistic with $n - 1$ degrees of freedom $\chi_W^2 = k(n - 1)W$. In this case, the test statistic of 7 is not significant.

W is constrained to lie between 0 (no agreement) and 1 (perfect agreement), but interpretation is difficult because it is unclear how much sense can be made of a statement such as 'the variance of the total ranks of entities was 25% of the maximum possible'. Significance tests are also relatively meaningless because the levels of agreement usually viewed as good in the social sciences are way above what would be required for significance. However, W can be converted into the mean **Spearman correlation coefficient** (see [2]):

$$\bar{r}_s = \frac{kW - 1}{k - 1}. \quad (7)$$

If we computed the Spearman correlation coefficient between all pairs of judges, this would be the average value. In this case, we would get $((4 \times 0.25) - 1)/3 = 0$. The clear interpretation here is that on average pairs of judges did not agree!

Kendall's Tau – τ

Kendall's tau, τ , like **Spearman's rho**, ρ is a measure of correlation based on ranks (see **Rank Based Inference**). It is useful when the raw data are themselves ranks, as for example job applicants, or when the data is ordinal. Examples of ordinal data include common rating scales based on responses ranging from 'strongly disagree' to 'strongly agree'.

Kendall's τ is based on the number of inversions (swaps) needed to get the ranks of both variables in the same or exactly the opposite order. For example, consider a data set with raw data pairs (20,17; 23,24; 28,25; 31,40; 90,26). Ranks of the X values are in order (1, 2, 3, 4, 5) and ranks of the corresponding Y values are (1, 2, 3, 5, 4). If the last two Y values are inverted (swapped), then ranks for X and Y will be identical.

Calculation

In order to calculate τ , it is first necessary to rank both the X and the Y variable. The number of inversions of ranks can then be counted using a simple diagram. The ranks of the X variables are ordered with the corresponding Y ranks underneath them. Then a line is drawn from each X rank to its corresponding Y rank. The number of inversions, I , will be equal to the number of crossing points. Two $N = 5$ examples are shown in Figure 1, with the relevant sequence of inversions in bold.

Example 1. Number of inversions, $I = 1$, $\tau = 0.80$

Raw X	20	23	28	31	90
Raw Y	17	24	25	40	26
Rank X	1	2	3	4	5
Rank Y	1	2	3	5	4
Invert 1	1	2	3	4	5

If the number of inversions is I , then τ is given by (1).

$$\tau = 1 - \frac{2I}{N(N-1)/2} \quad (1)$$

Equation (1) overestimates τ if there are ties. Procedures (cumbersome) for adjusting ties are given in [2]. Corrections for ties are implemented in standard statistical packages.

Hypothesis Testing

For the null hypothesis of no association, that is, $\tau = 0$ and $N > 10$, τ is approximately normally distributed with standard error, s_τ , given by (2)

$$s_\tau = \sqrt{\frac{2(2N+5)}{9N(N-1)}} \quad (2)$$

Accurate tables for $N \leq 10$ are provided by Kendall & Gibbons [2], but not used by many standard packages, for example, SPSS and JMP.

Confidence intervals and hypotheses about values of τ other than 0 can be obtained by noting that the Fisher transformation gives a statistic, z_r , that is normally distributed with variance $1/(N-3)$.

$$z_r = \frac{1}{2} \ln \left[\frac{1+\tau}{1-\tau} \right] \quad (3)$$

Comparison with Pearson's r and Spearman's ρ

For normally distributed data with a linear relation, parametric tests based on r (see **Pearson Product**

Example 2. Number of inversions, $I = 7$, $\tau = -0.60$

Raw X	20	23	28	31	90
Raw Y	40	24	25	26	17
Rank X	1	2	3	4	5
Rank Y	5	2	3	4	1
Invert 1	2	5	3	4	1
Invert 2	2	3	5	4	1
Invert 3	2	3	4	5	1
Invert 4	2	3	4	1	5
Invert 5	2	3	1	4	5
Invert 6	2	1	3	4	5
Invert 7	1	2	2	4	5

Figure 1 Examples of how to calculate the number of rank inversions in order to calculate τ

2 Kendall's Tau – τ

Moment Correlation) are usually more powerful than rank tests based on either τ or r_s . Authorities [1, 2] recommend τ over r_s as the best rank-based procedure, but r_s is far easier to calculate if a computer is not available. Kendall's τ has a simple interpretation – it is the degree to which the rankings of the two variables, X and Y , agree.

Kernel Smoothing

Kernel smoothing is a methodology for exposing structure or trend in data. It can be applied in a number of settings, including *kernel density estimation*, where the aim is to estimate the probability density underlying a variable, and *kernel regression*, where the aim is to estimate the conditional mean of a response variable given one or more covariates. Kernel smoothing is a nonparametric technique, in that it does not rely on the assumption of some particular parametric model for the data at hand. For instance, kernel regression does not rely on the existence of a linear (or other low degree polynomial) relationship existing between mean response and covariate. This makes kernel smoothing a powerful tool for **exploratory data analysis** and a highly applicable technique in circumstances where classical parametric models are clearly inappropriate.

Kernel Density Estimation

The problem of estimating a probability density function, or *density* for short, is a fundamental one in statistics. Suppose that we observe data $x_1, \dots, x_n$ on a single variable from which we wish to estimate the underlying density f . If we are willing to assume that f is of some given parametric form (e.g. normal, gamma), then the problem reduces to one of estimating the model parameters (e.g. mean μ and variance σ^2 in the normal case). This is a rather rigid approach in that the data play a limited role in determining the overall shape of the estimated density. Much greater flexibility is afforded by the **histogram**, which can be regarded as a simple nonparametric density estimator (when scaled to have unit area below the bars).

Although the histogram is widely used for data visualization, this methodology has a number of deficiencies. First, a histogram is not smooth, (typically) in contrast to the underlying density. Second, histograms are dependent on the arbitrary choice of *anchor point*; that is, the position on the x-axis at which the left hand edge of the first bin (counting from the left) is fixed. Third, histograms are dependent on the choice of bin width. We illustrate these problems using data on the age (in years) at onset of schizophrenia for a sample of 99 women. Four

histograms are displayed in Figure 1, using a variety of anchor points and bin widths. The importance of the anchor point is demonstrated by Figures 1(a) and 1(b), which differ only in a 2.5-year shift in the bin edges. The histogram shown in Figure 1(a) suggests that the distribution is skewed with a long right tail, whereas the histogram in Figure 1(b) indicates a bimodal structure. The effect of bin width is illustrated by comparing Figures 1(c) and 1(d) with the first pair of histograms. Notice that the thin bins in Figure 1(c) result in a rather noisy histogram, whereas the large bin width in Figure 1(d) produces a histogram that lacks the detail of Figures 1(a) and 1(b).

One may think of a histogram as being composed of rectangular building blocks. Each datum carries a block of area (or weight) $1/n$, which is centered at the middle of the bin in which the datum falls and stacked with other blocks in that bin. It follows that the histogram density estimate can be written as

$$\hat{f}_{\text{hist}}(x) = \sum_{i=1}^n \frac{1}{n} K(x - t_i) \quad (1)$$

where

$$K(x) = \begin{cases} \frac{1}{b} & -\frac{b}{2} < x \leq \frac{b}{2} \\ 0 & \text{otherwise} \end{cases} \quad (2)$$

in which b is the bin width and t_i is the midpoint of the bin in which x_i falls. An obvious generalization of (1) would be to replace t_i with x_i , so that each building block is centered at its respective data point rather than at a bin midpoint. The effect of this modification is illustrated in Figure 2(a), which shows the resulting estimate for the age at onset of schizophrenia data. (The data themselves are displayed as a *rug* on this plot.) Although this change solves the anchor point problem, the estimate itself remains jagged. We can obtain a smooth estimate by replacing the rectangular blocks by smooth functions or *kernels*. We then obtain the *kernel density estimate*,

$$\hat{f}(x) = \sum_{i=1}^n \frac{1}{nh} K\left(\frac{x - x_i}{h}\right), \quad (3)$$

where the kernel K is itself a smooth probability density function. Typically K is assumed to be unimodal and satisfy the conditions $K(x) = K(-x)$ and $\int K(x)x^2 dx = 1$; the normal density is a popular choice. The parameter h in (3) is usually called the

Figure 1 Histograms of age at onset of schizophrenia for a sample of 99 women. Histograms (a) and (b) both use a bin width of 5 years, but differ in anchor point. Histograms (c) and (d) use bin widths of 2.5 and 10 years respectively

bandwidth. It scales the kernel function and hence controls the smoothness of the density estimate in much the same manner as the bin width does in a histogram. Figures 2(b), 2(c), and 2(d) show kernel density estimates for the age data constructed using bandwidths $h = 10$, $h = 2$ and $h = 3.7$ respectively. The estimate in Figure 2(b) is oversmoothed, obscuring important structure in the data (particularly in the range 40–50 years), while estimate shown in Figure 2(c) is undersmoothed, leaving residual wiggles in the estimate. The degree of smoothing in the estimate in Figure 2(d) appears to be more appropriate. The shape of this final estimate (Figure 2(d)) suggests that the underlying distribution may be a mixture of two unimodal components, one centered at about 25 years and the other around 45 years. A commentary on the data and an analysis based on this type of model is given in **finite mixture distributions**.

As we have seen, kernel density estimation overcomes the deficiencies of the histogram in terms of smoothness and anchor point dependence, but

choosing an appropriate value for the bandwidth remains an issue. A popular approach to bandwidth selection is to seek to minimize the mean integrated squared error of $\hat{f}$:

$$\text{MISE}(h) = E \int \{\hat{f}(x; h) - f(x)\}^2 dx. \quad (4)$$

Here the notation $\hat{f}(x; h)$ emphasizes the dependence of the density estimate on h . Finding the minimizer, h_0 , of (4) is difficult in practice because $\text{MISE}(h)$ is a functional of the unknown target density f , and is awkward to manipulate from a mathematical perspective. A number of sophisticated methods for resolving these problems have been developed, amongst which the Sheather–Jones bandwidth selection technique is particularly well regarded [4]. The Sheather–Jones methodology was used to select the bandwidth for the density estimate in Figure 2(d).

Kernel density estimation has a wide variety of uses. It is a powerful tool for data visualization and exploration, and should arguably replace the

Figure 2 Kernel density estimates of age at onset of schizophrenia for a sample of 99 women. Estimate (a) is constructed using a rectangular kernel, while estimates (b), (c), and (d) use a normal kernel. The bandwidths in the last three estimates are $h = 10$, $h = 2$ and $h = 3.75$ respectively

histogram for this type of purpose. Kernel density estimates can also be used in **discriminant analysis**, **goodness-of-fit testing**, and testing for multimodality (or *bump hunting*) [5]. These applications often involve the multivariate version of (3); see [3] for details.

Kernel Regression

The data displayed in the **scatterplots** in Figure 3 are the annual number of live births in the United Kingdom from 1865 to 1914. Classical parametric regression models would struggle to represent the trend in these data because a linear or low-order polynomial (e.g. quadratic or cubic) fit is clearly inappropriate. The trouble with this approach to regression for these data is that one is required to

specify a functional form that describes the global behavior of the data, whereas the scatterplot displays a number of interesting features that are localized to particular intervals on the x-axis. For example, there is an approximately linear increase in births between 1865 and 1875, and a bump in the number of births between 1895 and 1910. This suggests that any model for the trend in the data should be local in nature, in that estimation at a particular year x_0 should be based only on data from years close to x_0 .

The preceding discussion motivates interest in the **nonparametric regression model**

$$Y_i = m(x_i) + \varepsilon_i \quad (i = 1, \dots, n), \quad (5)$$

where $x_1, \dots, x_n$ are covariate values, $Y_1, \dots, Y_n$ are corresponding responses, and $\varepsilon_1, \dots, \varepsilon_n$ are independent error terms with zero mean and common variance σ^2 . The regression function m describes

Figure 3 Kernel regression estimates for the UK birth data. (a) Displays the Nadaraya–Watson and local linear kernel estimates as solid and dashed lines respectively; both estimated were constructed with bandwidth $h = 1.61$. (b) Displays local linear kernel estimates obtained using bandwidths $h = 5$ (dashed line) and $h = 0.5$ (solid line)

the conditional mean of Y given x , and is a smooth function for which no particular parametric form is assumed. Local estimation of m may be achieved using a weighted average of the responses,

$$\hat{m}(x) = \frac{\sum_{i=1}^n w_i y_i}{\sum_{i=1}^n w_i}, \quad (6)$$

where the weights $w_1, \dots, w_n$ are selected so that w_i decreases as x_i becomes more distant from the estimation point x . The *Nadaraya–Watson* kernel regression estimator (originally proposed in [2] and [7]) defines the weights using kernel functions through

$$w_i = \frac{1}{h} K\left(\frac{x - x_i}{h}\right), \quad (7)$$

where K is typically a unimodal probability density with $K(x) = K(-x)$ and $\int K(x)x^2 dx = 1$, such as the standard normal density. Clearly (7) achieves the desired effect that data points with covariate distant to the estimation point x have negligible influence on the estimate. The bandwidth h scales the kernel in the same fashion as for density estimation. The Nadaraya–Watson regression estimate for the birth data is displayed as the solid line in Figure 3(a). It picks up the general trend in birth numbers through

time while smoothing out the haphazard year-to-year variation.

The Nadaraya–Watson estimator, for which we will use the specific notation $\hat{m}_0(x)$, may be derived in terms of a weighted least squares problem. Specifically, $\hat{m}_0(x) = \hat{\beta}_0$ where $\hat{\beta}_0$ minimizes

$$\sum_{i=1}^n (Y_i - \beta_0)^2 \frac{1}{h} K\left(\frac{x - x_i}{h}\right). \quad (8)$$

One may therefore think of the Nadaraya–Watson estimate at the point x as the result of fitting a constant regression function (i.e. just an intercept, β_0) by weighted least squares. We can generalize this approach by fitting a linear regression (see **Multiple Linear Regression**) at the point x , minimizing the revised weighted sum of squares

$$\sum_{i=1}^n (Y_i - \beta_0 - \beta_1(x_i - x))^2 \frac{1}{h} K\left(\frac{x - x_i}{h}\right). \quad (9)$$

If $\hat{\beta}_0, \hat{\beta}_1$ are the minimizers of (9), then the *local linear kernel regression estimate* at the point x , $\hat{m}_1(x)$, is defined by $\hat{m}_1(x) = \hat{\beta}_0$. The Nadaraya–Watson (or *local constant kernel*) estimate and the local linear kernel estimate often give rather similar results, but the latter tends to perform better close to edges of the data set. The local linear kernel estimate is displayed as a dashed regression line in Figure 3(a).

Although it is difficult to distinguish it from the Nadaraya–Watson estimate over most of the range of the data, close inspection shows that the local linear estimate follows the path of the data more appropriately at the extreme left hand end of the plot.

As with density estimation, the choice of bandwidth is crucial in determining the quality of the fitted kernel regression. An inappropriately large bandwidth will oversmooth the data and obscure important features in the trend, while a bandwidth that is too small will result in a rough, noisy kernel estimate. This is illustrated in Figure 3(b), where local linear kernel estimates were constructed using bandwidths $h = 5$ and $h = 0.5$ giving the dashed and solid lines respectively. A number of data driven methods for selecting h have been proposed, including a simple **cross-validation** approach that we now describe. Suppose we fit a kernel regression using all the data except the i th observation, and get an estimate $\hat{m}^{[-i]}(x; h)$, where the dependence on the bandwidth h has been emphasized in the notation. If h is a good value for the bandwidth, then $\hat{m}^{[-i]}(x_i; h)$ should be a good predictor of Y_i . It follows that the cross-validation function

$$CV(h) = \sum_{i=1}^n (\hat{m}^{[-i]}(x_i; h) - Y_i)^2 \quad (10)$$

is a reasonable performance criterion for h , and the minimizer $\hat{h}_{CV}$ of $CV(h)$ should be a suitable bandwidth to employ. This cross-validation approach was used to provide the bandwidth $h = 1.61$ for the local linear (and local constant) kernel estimates in Figure 3(a).

We have focused our attention on models with a single covariate, but kernel regression methods may be extended to cope with multiple covariates. For example, if the response Y is related to covariates x and z , then we might use a **general additive model** (GAM),

$$Y_i = m(x_i) + l(z_i) + \varepsilon_i \quad (i = 1, \dots, n), \quad (11)$$

where m and l are smooth regression functions which may be estimated using kernel methods. Alternatively, we may mix nonparametric and parametric terms to give a semiparametric regression model, such as

$$Y_i = m(x_i) + \beta z_i + \varepsilon_i \quad (i = 1, \dots, n). \quad (12)$$

Kernel methods may also be applied in **generalized linear models** to fit nonlinear terms in the linear predictor; see [1], for example.

Conclusions

Kernel methods can be used for nonparametric estimation of smooth functions in a wide variety of situations. We have concentrated on estimation of probability densities and regression functions, but kernel smoothing can also be applied to estimation of other functions in statistics such as spectral densities and hazard functions. There are now a number of books that provide a comprehensive coverage of kernel smoothing. Bowman and Azzalini's monograph [1] is recommended for those seeking an applications-based look at the subject, while Wand and Jones [6] provide a more theoretical (though still accessible) perspective. Both kernel density estimation and kernel regression methods are implemented in many software packages, including R, S-Plus, SAS, and Stata.

***k*-means Analysis**

Cluster analysis is a term for a group of multivariate methods that explore the similarities or differences between cases in order to find subgroups containing relatively homogenous cases (see **Cluster Analysis: Overview**). The cases may be, for example, patients with various symptoms, ideas arising from a focus group, clinics with different types of patient. There are two main types of cluster analysis: *optimization methods* that produce a single partition of the data, and **hierarchical clustering** which forms a nested series of mutually exclusive partitions or subgroups of the data. Divisions or fusions in hierarchical clustering, once made, are irrevocable. When an agglomerative algorithm has joined two cases they cannot subsequently be separated, and when a divisive algorithm has made a split they cannot be reunited. By contrast, optimisation cluster methods reallocate cases iteratively to produce a single *optimal* partition of the data into mutually exclusive clusters, and can therefore be used *inter alia* to correct for inefficient assignments made during hierarchical clustering.

Probably the most common optimisation method is *k*-means analysis, first described by Forgey [5], MacQueen [8] and Ball & Hall [2]. It has a compelling simplicity, namely, to find a partition of the cases into *k* clusters such that each case is closer to the mean of the cluster to which it is assigned than to any other cluster. However, it will be shown below that this simplicity conceals a computational flaw that does not guarantee convergence. For this reason we refer to it as ‘naïve’ *k*-means analysis. The method requires that a case *i* is moved from a cluster *p*, the cluster to which it is currently assigned, to another cluster *q* if the case is closer to the mean of cluster *q* than it is to the mean of cluster *p*; that is, if

$$d_{ip} > d_{iq}. \quad (1)$$

Naïve *k*-means analysis is usually implemented in software as follows:

1. Choose some initial partition of the cases into *k* clusters. This can be a tree section, for example, by hierarchical clustering, *k* selected ‘seed’ cases, or a random assignment of the cases to *k* clusters.
2. Compute the distance from every case to the mean of each cluster, and assign the cases to their nearest clusters.

3. Recompute the cluster means following any change of cluster membership at step 2.
4. Repeat steps 2 and 3 until no further changes of cluster membership occur in a complete iteration. The procedure has now converged to a stable *k*-cluster partition.

An Exact *k*-means Algorithm

It is a common misconception that *k*-means analysis, as described above, optimizes (i.e. minimizes) the *Euclidean Sum of Squares*, or trace (**W**), where **W** is the within-clusters dispersion matrix. The Euclidean Sum of Squares E_p for a cluster *p* is defined as:

$$E_p = \sum_{i \in p} n_i \sum_j (x_{ij} - \mu_{pj})^2, \quad (2)$$

where x_{ij} is the value of the *j*th variable for case *i* in cluster *p*, μ_{pj} is the mean of the *j*th variable for the *p*th cluster, and n_i is a weight for case *i* (usually 1).

The total Euclidean Sum of Squares is

$$E = \sum_p E_p. \quad (3)$$

The computational flaw in naïve *k*-means analysis arises from an incorrect assumption that if a case is moved to a cluster whose mean is closer than the mean of the cluster to which it is currently assigned, following test (1), then the move reduces *E*. This neglects to take account of the changes to the means of the clusters caused by reassigning the case. To minimize *E* unequivocally, a case should only be moved from a cluster *p* to another cluster *q* *if and only if the move reduces E* in (3). That is, iff:

$$E_p + E_q > E_{p-i} + E_{q+i}. \quad (4)$$

We call (4) the ‘exact assignment test’ for minimum *E*. It is not the same as assigning a case *i* to the nearest cluster mean, as in naïve *k*-means analysis, because moving any case from cluster *p* to cluster *q* also changes the means of *p* and *q*; and in certain circumstances, these changes may actually increase *E*. Rearranging (4) thus,

$$E_p - E_{p-i} > E_{q+i} - E_q, \quad (5)$$

which is equivalent to moving a case *i* from cluster *p* to cluster *q* iff:

$$I_{p-i,i} > I_{q,i}, \quad (6)$$

2 k -means Analysis

where $I_{p-i,i}$ is the increase in E resulting from the addition of case i to the complement $p-i$ of cluster p , and $I_{q,i}$ is the increase in E resulting from the addition of case i to cluster q . Beale [3] gives the increase I_{pq} in E on the union of two clusters p and q as follows:

$$I_{pq} = n_p n_q \sum_j \frac{(\mu_{pj} - \mu_{qj})^2}{(n_p + n_q)}, \quad (7)$$

where n_p and n_q are the sum of case weights of clusters p and q (usually their sizes), and μ_{pj} and μ_{qj} are the means of the clusters p and q for variable j . Upon substituting (7) for the comparison of a case i with clusters $p-i$ and q , (6) becomes

$$\frac{n_p n_i d_{pi}^2}{n_p - n_i} > \frac{n_q n_i d_{qi}^2}{n_q + n_i}. \quad (8)$$

Where the cases have equal weight, (8) simplifies to

$$\frac{n_p d_{pi}^2}{n_p - 1} > \frac{n_q d_{qi}^2}{n_q + 1}. \quad (9)$$

We refer to (8) as the ‘exact assignment test’ for k -means analysis. Since E is a sum of squares, and each reassignment that satisfies (8) actually reduces E by the difference between the two sides of (8), the procedure must converge in finite time. This is because E , being bounded by zero, cannot be indefinitely reduced.

It will be evident that the exact assignment test (8) or (9) is not equivalent to moving a case i from cluster p to cluster q if $d_{ip} > d_{iq}$, as in naïve k -means analysis, yet the naïve test is actually how k -means analysis is implemented in many software packages. In geometrical terms, moving a case i from cluster p to cluster q pulls the mean $\mu_{q+i,j}$ of q towards i and pushes the mean $\mu_{p-i,j}$ of p away from i . This causes the distances from the means of some cases in clusters p and q to increase, such that E may actually increase as a result of moving a case from cluster p to cluster q even if $d_{ip} > d_{iq}$. It does not usually happen with small data sets, but it can occur with large data sets where boundary cases may oscillate between two or more clusters in successive iterations and thereby the naïve procedure fails to converge.

This is why some standard k -means software also employ an *ad hoc* ‘movement of means’ convergence criterion. It stops the procedure when a complete iteration does not move a cluster centre by more than

a specified percentage, which must be greater than zero, of the smallest distance between any of the initial cluster centres. This is not a convergence criterion at all, but merely a computational device to prevent the program from oscillating between two or more solutions and hence iterating indefinitely. MacQueen [8] recognized this defect in his naïve k -means algorithm but failed to formulate the exact assignment test (8) that corrects for it. Anderberg [1] reports only the naïve k -means procedure. Hartigan [7] reports the exact assignment test for minimum E correctly, but curiously implements the naïve k -means test in the program listed in his appendix. Späth [9] correctly describes the exact assignment test for minimum E and implements it correctly in his program. Everitt et al. [4] give a worked example of naïve k -means analysis without mentioning the exact assignment test.

This important modification of the assignment test ensures that *exact* k -means analysis will always converge in finite time to a specific minimum E value, whereas *naïve* k -means analysis may only ever achieve interim higher values of E without actually converging. Furthermore, those k -means programs that utilize the ‘movement of means’ convergence criterion do not report the value of E because it can differ from one run to the next depending upon the order of the cases, the starting conditions and the direction in which the initial cluster means migrate.

A General Optimization Procedure

The exact assignment test can be generalized for any well-defined clustering criterion that is amenable to optimization, for example, to minimize the sum of within-group squared distances, similar to average-link cluster analysis in hierarchical clustering, or UPGMA. Another clustering criterion that has been proposed for binary variables is an information content statistic to be minimized by the relocation of a case from one cluster to another. The general procedure for optimization is now defined for any clustering criterion f to be minimized, as follows: Given any interim classification C of the cases, a case i currently assigned to a cluster p should be moved to another cluster q if:

$$f(C|i \in p) > f(C|i \in q). \quad (10)$$

The generalized exact assignment test (10) will always converge to a minimum f for a classification

C provided that there is a lower bound below which f cannot reduce further, such as zero as for the Euclidean Sum of Squares E specified in (2) and (3) because E is a sum of squares and for the within-cluster sum of squared distances.

Convergence

This does not necessarily mean that the final classification C obtained at convergence is *optimal*, since the *k*-means procedure will also converge to sub-optimal classifications that, nevertheless, satisfy the exact assignment test, see Table 1 below. For this reason, it is important to evaluate several different classifications obtained by *k*-means analysis for the same data, as advocated by Gordon [6]. Some writers have proposed fairly complex techniques for choosing initial seed points as the starting classification for *k*-means, and for combining and splitting clusters during the assignment process. Their general approach is to merge similar clusters or split heterogeneous clusters, with the object of finding a value of k , the best number of clusters, that yields a stable homogeneous classification. However, the choice of initial seed points, or the starting classification, can also be adequately tested by generating several random initial classifications, and it is open to the user to evaluate different values of k for the **number of clusters**.

It is well known that *k*-means analysis is also sensitive to the order in which the cases are tested for relocation, and some writers advocate varying this order randomly. Wishart [10] describes a FocalPoint *k*-means procedure that randomly rearranges the case order in each of a series of independent runs of the procedure. FocalPoint also generates a different random initial classification for each run. Randomisation

of the case order and the initial classification will generally yield different final classifications over the course of a number of trials. For example, in a study of 25 mammals described in terms of the composition of their milk, FocalPoint obtained 7 different stable classifications at the five-cluster level within 500 randomization trials, with values of E ranging from 2.58 to 3.45, as listed in Table 1. This is why it is important, firstly, to implement *k*-means analysis with the exact assignment test; and secondly, to pursue the optimisation procedure until it converges to a stable minimum E value that can be replicated. *k*-means programs that stop when a cluster centre does not move by more than a specified percentage of the smallest distance between any of the initial cluster centres will not necessarily converge to a stable, definitive E value. FocalPoint, by comparison, maintains a record of each classification obtained in a series of random trials, arranges them in ascending order of their E values, and counts the frequency with which each classification is replicated.

The results for 500 trials with the mammals milk data are given in Table 1, in which seven different stable classifications were found. The one corresponding to the smallest E value occurred in two-thirds of the trials and is almost certainly the global optimum solution for five clusters with these data. It is, however, instructive to examine the six suboptimal classifications, which find small clusters of one or two cases. Further examination reveals these to be outliers, so that the procedure has in effect removed the outliers and reduced the value of k resulting in larger clusters of 10 or 11 cases elsewhere. There is always the possibility that *k*-means analysis will find singleton clusters containing outliers, because such clusters contribute zero to the sum of squares E and therefore once separated they cannot be reassigned. There is, therefore, a case for creating a separate residue set of outliers.

In Clustan software, Wishart [10, 11], a residue set can be created by specifying a threshold distance d^* above which a case cannot be assigned to a cluster. Thus, if $d_{ip} > d^*$, the case is deemed too remote to be assigned to cluster p and is instead placed in the residue. Another possibility is to specify a percentage r , such as $r = 5\%$, and to place the 5% of the cases that are most remote from any cluster in the residue set. This requires additional work to

Table 1 Seven stable classifications found for 25 mammals by *k*-means analysis in 500 random trials, with cluster sizes, final E values and frequencies

Classification	Cluster sizes	E	Frequency
1	8,6,5,4,2	2.58	336
2	10,7,5,2,1	2.81	49
3	10,7,4,2,2	2.93	4
4	9,7,6,2,1	2.946	101
5	11,6,4,2,2	2.952	2
6	10,8,5,1,1	3.38	3
7	11,6,6,1,1	3.45	5

store the distances of the cases to their nearest cluster and at the completion of each iteration to order the distances, reallocate those cases corresponding to $r\%$ largest distances to the residue set, and recalculate the cluster means.

Comparison of *k*-means with Other Optimisation Methods

Some writers argue that *k*-means analysis produces spherical clusters that can be distorted by the presence of outliers, and advocate instead a search for elliptical clusters by fitting an underlying mixture of multivariate normal distributions (*see Finite Mixture Distributions; Model Based Cluster Analysis*). The choice of method really depends upon the object of the analysis – for example, whether one is seeking ‘natural’ classes or a more administrative classification. Suppose, for example, the cases are individuals described solely by their height and weight. A search for ‘natural’ clusters should only find one class, with the data fitting a single elliptical bivariate normal distribution (*see Catalogue of Probability Density Functions*). By comparison, *k*-means analysis will find any number of spherical

clusters throughout the distribution, a kind of mapping of the distribution. It will therefore separate, for example, ballerinas and sumo wrestlers, infants and adults, a summarization of the data rather than a ‘natural’ classification. The decision to use *k*-means analysis therefore depends upon the type of clusters that are sought – should they be such that any cluster of individuals are *all* similar in terms of all of the variables; or is variation allowed in some of the variables. Model-based clustering is suitable for the latter, whereas *k*-means analysis would suffice for the former.

Another goal for *k*-means analysis is the summarization of a large quantity of data, such as occur in data mining or remote sensing applications. The goal here is to reduce a large amount of data to manageable proportions by simplifying 200,000 cases in terms of 1000 clusters averaging 200 cases each. In this example, each cluster would comprise a set of individuals that are all very similar to each other, and a single exemplar can be selected to represent each cluster. The data are now described in terms of 1000 different cases that map the whole population in terms of all of the variables. Further modeling can more easily be undertaken on the 1000 exemplars than would be feasible on 200,000 individuals.

Figure 1 Dendrogram for *k*-means analysis at five clusters with two outliers (elephant and rabbit)

Dendrogram for *k*-means

Optimization methods such as *k*-means analysis generally yield a single partition of a set of n cases into k clusters. This says nothing about the relationships between the k clusters, or about the relationships between the cases assigned to any one cluster. A summary tree has therefore been implemented in ClustanGraphics [10] that shows these relationships, as illustrated in Figure 1.

A five-cluster solution for the 25 mammals data was obtained using ‘exact’ *k*-means analysis, as shown in Table 1. An outlier threshold was specified that caused two cases (elephant and rabbit) to be excluded from the classification as outliers. A subtree is now constructed for each cluster that shows how the members of that cluster would agglomerate to form it; and a supertree is constructed to show how the clusters would agglomerate hierarchically by Ward’s method. The resulting tree is shown in Figure 1, with the cluster exemplars underlined.

When using *k*-means analysis it is important also to use Ward’s method to construct the agglomerative tree for exact *k*-means analysis, because both methods optimize the Euclidean Sum of Squares. This is an excellent way of representing the structure around a *k*-means cluster model for a small data set. However, with larger data sets a full tree can become unwieldy, and therefore it is easier to restrict it to the final supertree agglomeration of k clusters.

Kolmogorov, Andrey Nikolaevich

Born: April 25, 1903, in Tambov, Russia.

Died: October 20, 1987, in Moscow, Russia.

Andrey Nikolaevich Kolmogorov was born in Russia in 1903 and was raised by his aunt when his mother died in childbirth and his father was in exile. After a traditional schooling, Kolmogorov worked as a conductor on the railway. His educational background must have been excellent, however, because in his spare time he wrote a treatise on Newton's laws of mechanics, though he had not yet attended university. Kolmogorov enrolled in Moscow State University in 1920 and studied a number of subjects, including metallurgy, Russian history, and mathematics. He published his first paper two years later, and at the time of his graduation in 1925 he published eight more, including his first paper on probability.

By the time Kolmogorov completed his doctorate in 1929, he had 18 publications to his credit. Two years later, he was appointed a professor at Moscow University. The same year, he published a paper entitled *Analytical methods in probability theory*, in which he laid out the basis for the modern theory of Markov processes (see **Markov Chains**). Two years after that, in 1933, he published an axiomatic treatment of probability theory. Over the next few years, Kolmogorov and his collaborators published a long series of papers. Among these was a paper in which he developed what is now known as the **Kolmogorov-Smirnov test**, which is used to test the goodness of fit of a given set of data to a theoretical distribution. Though Kolmogorov's contributions to statistics are numerous and important, he was a mathematician, and not a statistician. Within mathematics, his range was astounding. Vitanyi [1] cited what he called

a 'nonexhaustive' list of the fields in which Kolmogorov worked:

'The theory of trigonometric series, measure theory, set theory, the theory of integration, constructive logic (intuitionism), topology, approximation theory, probability theory, the theory of random processes, information theory, mathematical statistics, dynamical systems, automata theory, theory of algorithms, mathematical linguistics, turbulence theory, celestial mechanics, differential equations, Hilbert's 13th problem, ballistics, and applications of mathematics to problems of biology, geology, and the crystallization of metals.

In over 300 research papers, textbooks and monographs, Kolmogorov covered almost every area of mathematics except number theory. In all of these areas even his short contributions did not just study an isolated question, but in contrast exposed fundamental insights and deep relations, and started whole new fields of investigations.'

Kolmogorov received numerous awards throughout his life and earned honorary degrees from many universities. He died in Moscow in 1987.

Kolmogorov–Smirnov Tests

The Kolmogorov–Smirnov and Smirnov Tests

The Kolmogorov–Smirnov test is used to test the goodness of fit of a given set of data to a theoretical distribution, while the Smirnov test is used to determine if two samples appear to follow the same distribution. Both tests compare cumulative distribution functions (*cdfs*). The problem of determining whether a given set of data appear to have been drawn from a known distribution is often of interest only because it has implications for the subsequent statistical analysis. For example, one may test a given distribution for normality, and if one fails to reject this hypothesis, then one may proceed as if normality were proven and use a parametric analysis that relies on normality for validity. This two-stage approach is problematic, because it confuses failure to reject a null hypothesis (in this case, normality) with proving its truth [10]. The consequence of this error is that the true Type I error rate may then exceed the nominal Type I error rate [1, 6], which is often taken to be 0.05.

The Smirnov Test

The problem of determining whether two sets are drawn from the same distribution functions arises naturally in many areas of research and, in contrast with the problem of fitting a set of data to a known theoretical distribution, is often of intrinsic interest. For example, one may ask if scores on a standardized test are the same in two different states or in two different counties. Or one may ask if within a family the incidence of chicken pox is the same for the first-born child and the second-born child. Formally, we can state the problem as follows:

Let $x:(x_1, x_2, \dots, x_m)$ and $y:(y_1, y_2, \dots, y_n)$ be independent random samples of size m and n , respectively, from continuous or ordered categorical populations with *cdfs* of F and G , respectively. We wish to test the null hypothesis of equality of distribution functions:

$$H_0: F(t) = G(t), \text{ for every } t. \quad (1)$$

This null hypothesis can be tested against the omnibus two-sided alternative hypothesis:

$$H_a: F(t) \neq G(t) \text{ for at least one value of } t, \quad (2)$$

or it can be tested against a one-sided alternative hypothesis:

$$H_a: F(t) \geq G(t) \text{ for all values of } t, \text{ strictly greater for at least one value of } t, \quad (3)$$

or

$$H_a: F(t) \leq G(t) \text{ for all values of } t, \text{ strictly smaller for at least one value of } t. \quad (4)$$

To compute the Smirnov test statistic, we first need to obtain the empirical *cdfs* for the x and y samples. These are defined by

$$F_m(t) = \frac{\text{number of sample } x\text{'s } \leq t}{m} \quad (5)$$

and

$$G_n(t) = \frac{\text{number of sample } y\text{'s } \leq t}{n}. \quad (6)$$

Note that these empirical *cdfs* take the value 0 for all values of t below the smallest value in the combined samples and the value 1 for all values of t at or above the largest value in the combined samples. Thus, it is the behavior between the smallest and largest sample values that distinguishes the empirical *cdfs*. For any value of t in this range, the difference between the two distributions can be measured by the signed differences, $[F_m(t) - G_n(t)]$ or $[G_n(t) - F_m(t)]$, or by the absolute value of the difference, $|F_m(t) - G_n(t)|$. The absolute difference would be the appropriate choice where the alternative hypothesis is nondirectional, $F(t) \neq G(t)$, while the choice between the two signed differences depends on the direction of the alternative hypothesis. The value of the difference or absolute difference may change with the value of t . As a result, there would be a potentially huge loss of information in comparing distributions at only one value of t [3, 14, 17].

The Smirnov test resolves this problem by employing as its test statistic, D , the maximum value of the selected difference between the two empirical cumulative distribution functions:

$$D = \max |F_m(t) - G_n(t)|, \quad \min(x, y) \leq t \leq \max(x, y), \quad (7)$$

2 Kolmogorov–Smirnov Tests

where the alternative hypothesis is that $F(t) \neq G(t)$,

$$D^+ = \max[F_m(t) - G_n(t)],$$

$$\min(x, y) \leq t \leq \max(x, y), \quad (8)$$

where the alternative hypothesis is that $F(t) > G(t)$ for some value(s) of t , and

$$D^- = \max[G_n(t) - F_m(t)],$$

$$\min(x, y) \leq t \leq \max(x, y), \quad (9)$$

where the alternative hypothesis is that $F(t) < G(t)$ for some value(s) of t . Note, again, that the difference in empirical *cdf*s need be evaluated only for the set of unique values in the samples x and y .

To test H_0 at the α level of significance, one would reject H_0 if the test statistic is large, specifically, if it is equal to or larger than D_α . The Smirnov test has been discussed by several authors, among them Hilton, Mehta, and Patel [11], Nikiforov [15], and Berger, Permutt, and Ivanova [7]. One key point is that the exact permutation reference distribution (see **Exact Methods for Categorical Data**) should be used instead of an approximation, because the approximation is often quite poor, [1, 6]. In fact, in analyzing a real set of data, Berger [1] found enormous discrepancies between the exact and approximate Smirnov tests for both the one-sided and the two-sided P values. Because of the discreteness of the distribution of sample data, it generally will not be possible to choose D_α to create a test whose significance level is exactly equal to a prespecified value of α . Thus, D_α should be chosen from the permutation reference distribution so as to make the Type I error probability no greater than α .

For any value of t , the two-sample data can be fit to a 2×2 table of frequencies. The rows of the table correspond to the two populations sampled, X and Y , while the columns correspond to response magnitudes – responses that are no larger than t in one column and responses that exceed t in a second column. Taken together, these tables are referred to as the *Lancaster decomposition* [3, 16]. Such a set of tables is unwieldy where the response is continuously measured, but may be of interest where the response is one of a small number of ordered categories, for example, unimproved, slightly improved, and markedly improved. In this case, the Smirnov D can be viewed as the maximized Fisher exact

test statistic – the largest difference in success proportions across the two groups, as the definition of success varies over the set of Lancaster decomposition tables [16]. Is D maximized when success is defined as either slightly or markedly improved, or when success is defined as markedly improved?

The row margins, sample sizes, are fixed by the design of the study. The column margins are complete and sufficient statistics under the equality null hypothesis. Hence, the exact analysis would condition on the two sets of margins [8]. The effect of conditioning on the margins is that the permutation sample space is reduced compared to what it would be with an unconditional approach. Berger and Ivanova [4] provide S-PLUS code for the exact conditional computations; see also [13, 18, 19]. The Smirnov test is invariant under reparameterization of x . That is, the maximum difference D will not change if x undergoes a monotonic transformation. So the same test statistic D results if x is analyzed or if $\log(x)$ or some other transformation, such as the square of x , is analyzed; hence, the P value remains the same too.

The Smirnov test tends to be most sensitive around the median value where the cumulative probability equals 0.5. As a result, the Smirnov test is good at detecting a location shift, especially changes in the median values, but it is not always as good at detecting a scale shift (spreads), which affects the tails of the probability distribution more, and which may leave the median unchanged. The **power** of the Smirnov test to detect specific alternatives can be improved in any of several ways. For example, the power can be improved by refining the Smirnov test so that any ties are broken. Ties result from different tables in the permutation reference distribution having the same value of the test statistic.

There are several approaches to breaking the ties, so that at least some of the tables that had been tied are now assigned distinct values of the test statistic [12, 16]. Only one of these approaches represents a true improvement in the sense that even the exact randomized version of the test becomes uniformly more powerful [8]. Another modification of the Smirnov test is based on recognizing its test statistic to be a maximized difference of a constrained set of linear rank test statistics, and then removing the constraint, so that a wider class of linear rank test statistics is considered in the maximization [5].

The power of this adaptive omnibus test is excellent.

While there do exist tests that are generally or in some cases even uniformly more powerful than the Smirnov test, the Smirnov test still retains its appeal as probably the best among the simple tests that are available in standard software packages (the exact Smirnov test is easily conducted in StatXact). One could manage the conservatism of the Smirnov test by reporting not just its P value but also the entire P value interval [2], whose upper end point is the usual P value but whose lower end point is what the P value would have been without any conservatism.

The Kolmogorov–Smirnov Test

As noted above, the Kolmogorov–Smirnov test assesses whether a single sample could have been sampled from a specified probability distribution. Letting $G_n(t)$ be the empirical cdf for the single sample and $F(t)$ the theoretical cdf – for example, Normal with mean μ and variance σ^2 – the Kolmogorov–Smirnov test statistic takes one of these forms:

$$D_k = \max |F(t) - G_n(t)|, \\ \min(x) \leq t \leq \max(x), \quad (10)$$

where the alternative hypothesis is that $F(t) \neq G(t)$,

$$D_k^+ = \max[F(t) - G_n(t)], \\ \min(x) \leq t \leq \max(y), \quad (11)$$

where the alternative hypothesis is that $F(t) > G(t)$ for some value(s) of t , and

$$D_k^- = \max[G_n(t) - F(t)], \\ \min(x) \leq t \leq \max(x), \quad (12)$$

where the alternative hypothesis is that $F(t) < G(t)$ for some value(s) of t .

The Kolmogorov–Smirnov test has an exact null distribution for the two directional alternatives but the distribution must be approximated for the nondirectional case [9]. Regardless of the alternative, the test is less accurate if the parameters of the theoretical distribution have been estimated from the sample.

Kruskal–Wallis Test

The nonparametric Kruskal-Wallis test [5] and [6] is an extension of the **Wilcoxon-Mann-Whitney test**. The null hypothesis is that the k populations sampled have the same average (median). The alternative hypothesis is that at least one sample is from a distribution with a different average (median). This test is an alternative to the parametric one-way **analysis of variance F test**.

Assumptions

The samples are assumed to be independent of each other, the populations are continuously distributed, and there are no tied values. Monte Carlo results by Fay and Sawilowsky [3] and Fay [4] indicated that the best techniques for resolving tied values are (a) assignment of midranks or (b) random assignment of tied values for or against the null hypothesis.

Procedure

Rank all the observations in the combined samples, keeping track of the sample membership. Compute the rank sums of each sample. Let R_i equal the sum of the ranks of the i th sample of sample size n_i . The logic of the test is that the ranks should be randomly distributed among the k samples.

Test Statistic

The computational formula for the test statistic, H , is

$$H = \frac{12}{N(N+1)} \sum_{i=1}^k \frac{R_i^2}{n_i} - 3(N+1) \quad (1)$$

where N is the total sample size, n_i is the size of the i th group, k is the number of groups, and R_i is the rank-sum of the i th group. Reject H_0 when $H \geq$ critical value.

Large Sample Sizes

For large sample sizes, the null distribution is approximated by the χ^2 distribution with $k - 1$ degrees

of freedom. Thus, the rejection rule is to reject H_0 if $H \geq \chi_{\alpha, k-1}^2$, where $\chi_{\alpha, k-1}^2$ is the value of χ^2 at nominal α with $k - 1$ degrees of freedom. Monte Carlo simulations conducted by Fahoome and Sawilowsky [2] and Fahoome [1] indicated that the large sample approximation requires a minimum sample size of 7 when $k = 3$, and 14 when $k = 6$, for $\alpha = 0.05$.

Example

The Kruskal-Wallis statistic is calculated using the following five samples, $n_1 = n_2 = n_3 = n_4 = n_5 = 15$ (Table 1).

Table 1 Data set for five samples

Sample 1	Sample 2	Sample 3	Sample 4	Sample 5
4	5	5	4	2
6	8	7	10	4
9	9	7	10	9
13	11	8	13	10

638	595	441.5	656.5	519

2 Kruskal–Wallis Test

Table 3 Ranked sums for five samples

	R_i	$(R_i)^2$
R_1	638.0	407,044.00
R_2	595.0	354,025.00
R_3	441.5	194,922.25
R_4	656.5	430,992.25
R_5	519.0	269,361.00
		1,656,344.50

The combined samples were ranked, and tied ranks were assigned average ranks (Table 2).

The rank sums are: $R_1 = 638$, $R_2 = 595$, $R_3 = 441.5$, $R_4 = 656.5$, and $R_5 = 519$. The sum of $R_i^2 = 1,656,344.50$ (Table 3).

$H = 12/75 \cdot 76 (1,656,344.5/15) - 3 \cdot 76 = 0.00211(110, 422.9667) - 228 = 4.4694$. The H statistic is 4.4694. Because H is less than the critical value for H at $\alpha = 0.05$, $n = 15$, and $k = 5$, the null hypothesis cannot be rejected. The large sample approximation is 9.488, which is Chi-square with $5 - 1 = 4$ degrees of freedom at $\alpha = 0.05$. Because $4.4694 < 9.488$, the null hypothesis cannot be rejected on the basis of the evidence from these samples.

Kurtosis

Karl Pearson [6] defined a distribution's degree of kurtosis as $\eta = \beta_2 - 3$, where $\beta_2 = \sum (X - \mu)^4 / n\sigma^4$, the expected value of the distribution of Z scores which have been raised to the 4th power. β_2 is often referred to as 'Pearson's kurtosis', and $\beta_2 - 3$ (often symbolized with γ_2) as 'kurtosis excess' or 'Fisher's kurtosis', even though it was Pearson who defined kurtosis as $\beta_2 - 3$. An unbiased estimator for γ_2 is $g_2 = n(n+1) \sum Z^4 / (n-1)(n-2)(n-3) - 3(n-1)^2 / (n-2)(n-3)$. For large sample sizes ($n > 1000$), g_2 may be distributed approximately normally, with a standard error of approximately $\sqrt{(24/n)}$ [7]. While one could use this sampling distribution to construct confidence intervals for or tests of hypotheses about γ_2 , there is rarely any value in doing so.

Pearson [6] introduced kurtosis as a measure of how flat the top of a symmetric distribution is when compared to a normal distribution of the same variance. He referred to distributions that are more flat-topped than normal distributions ($\gamma_2 < 0$) as 'platykurtic', those less flat-topped than normal ($\gamma_2 > 0$) as 'leptokurtic', and those whose tops are about as flat as the tops of normal distributions as 'mesokurtic' ($\gamma_2 \approx 0$).

Kurtosis is actually more influenced by scores in the tails of the distribution than scores in the center of a distribution [3]. Accordingly, it is often appropriate to describe a leptokurtic distribution as 'fat in the tails' and a platykurtic distribution as 'thin in the tails.'

Moors [5] demonstrated that $\beta_2 = \text{Var}(Z^2) + 1$. Accordingly, it may be best to treat kurtosis as the extent to which scores are dispersed away from the shoulders of a distribution, where the shoulders are the points where $Z^2 = 1$, that is, $Z = \pm 1$. If one starts with a normal distribution and moves scores from the shoulders into the center and the tails, keeping variance constant, kurtosis is increased. The distribution will probably appear more peaked in the center and fatter in the tails, like a Laplace distribution ($\gamma_2 = 3$) or a Student's t with few degrees of freedom ($\gamma_2 = 6/(df - 4)$). Starting again with a normal distribution, moving scores to the shoulders from the center and the tails will decrease kurtosis. A uniform distribution certainly has a flat top

with $\gamma_2 = 1.2$, but γ_2 can reach a minimum value of -2 when two score values are equally probable and all other score values have probability zero (a rectangular U distribution, that is, a binomial distribution with $n = 1, p = .5$). One might object that the rectangular U distribution has all of its scores in the tails, but closer inspection will reveal that it has no tails, and that all of its scores are in its shoulders, exactly one standard deviation from its mean. Values of g_2 less than that expected for a uniform distribution (-1.2) may suggest that the distribution is bimodal [2], but bimodal distributions can have high kurtosis if the modes are distant from the shoulders.

Kurtosis is usually of interest only when dealing with approximately symmetric distributions. **Skewed** distributions are always leptokurtic [4]. Among the several alternative measures of kurtosis that have been proposed (none of which has often been employed) is one which adjusts the measurement of kurtosis to remove the effect of skewness [1].

While it is unlikely that a behavioral researcher will be interested in questions that focus on the kurtosis of a distribution, estimates of kurtosis, in combination with other information about the shape of a distribution, can be useful. DeCarlo [3] described several uses for the g_2 statistic. When considering the shape of a distribution of scores, it is useful to have at hand measures of skewness and kurtosis, as well as graphical displays. These statistics can help one decide which estimators or tests should perform best with data distributed like those on hand. High kurtosis should alert the researcher to investigate outliers in one or both tails of the distribution.

Laplace, Pierre Simon (Marquis de)

Born: March 23, 1749, in Normandy, France.

Died: March 5, 1827, in Paris, France.

From the early years of the 19th century, Laplace became recognized as a mathematical genius, astronomer, and pioneer in the growing discipline of statistics. Napoleon had a genuine interest in science and mathematics, which helped to increase their standing in France. Such support from Napoleon no doubt enhanced the reputation of Laplace in particular. Given these circumstances, **Adolphe Quételet** travelled from Belgium to Paris in 1823. He learned observational astronomy and, from Laplace, received some informal instruction on mathematical probability and its application.

At the age of 17, Laplace attended the University of Caen where he distinguished himself as a mathematician. In 1767, he went to Paris, and here he was appointed professor at the Ecole Militaire. He became a member of the Bureau des Longitudes from its inception in 1795 and a member of the Observatory, which dated from the 17th century. Both were prominent research institutions for mathematical and astronomical studies. Laplace took a leading part in the Bureau, where he encouraged others to investigate his own research problems. He also became an examiner at the Ecole Normale, another prestigious intellectual French institution in Paris. Laplace became a member of the Académie Royale des Sciences, which from 1795 was named the *l'Institut National* [1]. Such was the prestige of the sciences that they were categorized as 'First Class', and in 1816 the Académie des Sciences were granted the power to recommend and appoint further members. Laplace became one of its key figures and, moreover, enjoyed the patronage of Napoleon, which benefited not only Laplace himself but also the standing of science in general. Thus, Laplace was enabled to exert his own influence. For example, he persuaded Baron

Montyon that statistics deserved special attention. When the Académie decided to award a statistics prize, this relatively new subject became recognized as an additional independent branch of science. Furthermore, as Joseph Fourier (1768–1830) pointed out, statistics was not to be confused with political economy.

One of the first works of Laplace was 'Mémoire sur la Probabilité des Causes par les Evénements' (1774); in this work, he announced his 'principe' as that of inverse probability, giving recognition to the earlier work of **Jean Bernoulli**, which he had not seen. This principle provided a solution to the problem of deciding upon a mean on the basis of several observations of the same phenomenon. In 1780, he presented to the Académie 'Mémoire sur la Probabilité', published in 1781. According to Stigler, these publications 'are among the most important and most difficult works in the history of mathematical probability' ([3, p. 100], see also [2]). In 1809, he then read 'Sur les Approximations des Formules qui sont Fonctions de très-grands Nombres', published the following year. The 'Supplément' to this memoir contained his statement of a **central limit theorem**. Among other works for which Laplace is best known is his 'Exposition du Système du Monde' of 1796, a semipopular work. He dedicated his work on astronomical mathematics, 'Traité de Mécanique Céleste' to Napoleon, which was published in four volumes between 1799 and 1805. In 1812, he presented 'Théorie Analytique des Probabilités' to the First Class of the Académie. This was followed by 'Essai Philosophique' in 1814.

Latent Class Analysis

Latent class analysis provides a model for data involving categorical variables that assumes that the observed relationships between the variables arise from the presence of an underlying categorical or ‘grouping’ variable for the observations, with, within each group, the variables being independent of one another, the so-called *conditional independence* assumption. Overviews of latent class analysis are given in [1, 4], but essentially the model involves postulating a **finite mixture distribution** for the data, in which the component densities are multivariate Bernoulli (see **Catalogue of Probability Density Functions**). For binary observed variables, the latent class model assumes that the underlying latent variable has c categories and that in the i th category, the probability of a ‘1’ response on variable j is given by

$$\Pr(x_{ij} = 1 | \text{group } i) = \theta_{ij}, \quad (1)$$

where x_{ij} is the value taken by the j th variable in group i . From the conditional independence assumption, it follows that the probability of an observed vector of responses, $\mathbf{x}' = [x_{i1}, x_{i2}, \dots, x_{iq}]$, where q is the number of observed variables is given by

$$\Pr(\mathbf{x} | \text{group } i) = \prod_{j=1}^q \theta_{ij}^{x_{ij}} (1 - \theta_{ij})^{1-x_{ij}}. \quad (2)$$

The proportions of each category in the population are assumed to be $p_1, p_2, \dots, p_c$, with $\sum_{i=1}^c p_i = 1$, leading to the following unconditional density function for the observed vector of responses $\mathbf{x}$

$$\Pr(\mathbf{x}) = \sum_{i=1}^c p_i \prod_{j=1}^q \theta_{ij}^{x_{ij}} (1 - \theta_{ij})^{1-x_{ij}}. \quad (3)$$

The parameters of this density function, the p_i and the θ_{ij} are estimated by **maximum likelihood**, and the division of observations into the c categories made by using the maximum values of the estimated posterior probabilities (see **Finite Mixture Distributions**). For examples of the application of latent class analysis see, for example, [2, 3].

Latent Transition Models

During the twentieth century, a considerable number of **panel studies** have been carried out, making short **time series** of three or more measurements available for large numbers of subjects. This raised the question how to describe stability and change in the categorical variables typical in these surveys, relating to socioeconomic, medical, marketing, and other issues. The description of flows between the states of these variables for discrete periods of time turned out to be an intuitively appealing approach.

The foundation for these models was laid by the Russian mathematician **Andrei A. Markov (1856–1922)** who formulated a simple model for a sequence of discrete distributions in time. He supposed that history is irrelevant except for the previous state, and showed that a system with predictable behavior emerges. As an example, we will take employment status, with three states: employed, E, unemployed, U, and out of the labor force, O. Suppose this variable is measured at several successive quarters in a random sample of size 10 000. Ignoring births and deaths for simplicity, turnover as in Table 1 could be observed.

The assumption of the **Markov chain** is that the process has no memory. Only the initial state proportions matter for the prediction of the distribution at the next occasion. Prediction is possible by using the transition probabilities, the probabilities of being in each of the possible states at the next time point, given the state currently occupied. After multiplication of the initial state proportions with the corresponding transition probabilities and summation of resulting products that relate to the same employment status at the next time point, the distribution of the next time point is obtained; that is, $0.4 \times 0.97 + 0.1 \times 0.05 + 0.5 \times 0.01$ for the number of employed at the next occasion, a slight decrease to 39.8% compared to the initial 40%. Once the distribution for the next occasion is obtained, the distribution for one period ahead in time can be predicted, provided that the Markov chain is stationary, that is, transition probabilities are still the same.

When the Markov assumption holds for a stationary chain, the initial distribution will gradually converge to equilibrium as more and more periods pass. This means that, in the long run, the probability of being in a specific state becomes independent of the initial state, that is, the matrix of probabilities that describe the transition from initial states to states many periods later forms a matrix with equal rows. It can be computed by matrix multiplication of the matrix with one-period transition probabilities, **T**, with **T** itself and the result again with **T**, and so on until all rows of the resulting matrix are the same. For the example data, it will take several dozens of years to reach the equilibrium state, 33% employed, 8% unemployed, and 59% out of the labor force.

Social science data generally exhibit less change in the long run than a Markov chain predicts. With respect to labor market transitions, the Markov property is not realistic because of heterogeneity within states with respect to the probability of changing state. People out of the labor force are not homogeneous; retired people will generally have a low probability of reentering the labor force, and students have a much higher probability of entering it. People who are employed for several periods have a higher probability of remaining employed than those who have recently changed jobs, and so on. Blumen et al. [1] introduced a model with a distinction between people who change state according to a Markov chain, the movers, and people who remain in the same state during the observation periods, the stayers.

The example in Table 2 shows a population that can be split up in 25% movers and 75% stayers. However, the distinction between movers and stayers is not observed. It is a **latent variable**, whose distribution can be estimated with panel data on three or more occasions and an appropriate model [4]. As the proportion of stayers is a model parameter, this mover–stayer model can accommodate data with little change, especially little long-term change.

Another more realistic model is the latent Markov model. As the mover–stayer model, it predicts less long-term change than the simple Markov chain. It is due to Wiggins [13], based on his 1955 thesis, and Lazarsfeld and Henry [6]. According to the latent Markov model, observed change is partly due to **measurement error**, also called *response uncertainty* or *unreliability*. The model separates measurement error from latent change, also called *indirectly measured change*. In Table 3, a cross-table is conceived that

2 Latent Transition Models

Table 1 A cross-table of successive measurements viewed as one transition of a Markov chain

Initial state	Initial state proportions	State next quarter					
		Frequencies			Transition probabilities		
		E	U	O	E	U	O
Employed, E	0.40	3880	40	80	0.97	0.01	0.02
Unemployed, U	0.10	50	880	70	0.05	0.88	0.07
Out of labor force, O	0.50	50	50	4900	0.01	0.01	0.98

Table 2 Separation of movers and stayers, a latent, indirectly measured, distinction of types

		State next quarter					
		Frequencies			Transition probabilities		
Initial state	Initial state proportions	E	U	O	E	U	O
Movers, 25%							
Employed, E	0.10	380	40	80	0.76	0.08	0.16
Unemployed, U	0.05	50	380	70	0.10	0.76	0.14
Out of labor force, o	0.10	50	50	400	0.10	0.10	0.80
Stayers, 75%							
Employed, E	0.30	3500	0	0	1	0	0
Unemployed, U	0.05	0	500	0	0	1	0
Out of labor force, o	0.40	0	0	4500	0	0	1

Table 3 Measurement error and latent, indirectly measured, transitions both explain observed change

Latent initial state	Latent initial state proportions	Observed (same quarter)			Latent state next quarter		
		Response probabilities			Transition probabilities		
		E	U	O	E	U	O
Proportions							
Employed, E	0.40	0.992	0.004	0.004	0.97	0.01	0.02
Unemployed, U	0.10	0.04	0.92	0.04	0.11	0.76	0.13
Out of labor force, o	0.50	0.003	0.005	0.992	0.01	0.01	0.98
Frequencies							
Employed, E	4000	3972	15	14	3899	29	72
Unemployed, U	500	18	312	20	55	382	63
Out of labor force, o	5000	17	23	4960	59	41	4900

relates the indirectly measured, latent, initial labor market status with the observed labor market status. This cross-table holds the probabilities of a specific response, given the indirectly measured, latent status. For instance, the probability that unemployed will erroneously be scored as out of the labor force is 20/500 or 0.04.

The latent Markov model has a local independence assumption. Response probabilities only depend on

the present latent state, not on previous states or on other variables. Moreover, a Markovian process is assumed for the latent variables. With these assumptions, the latent Markov model can be estimated from panel data on three or more occasions, that is, from many observations on few time points. MacDonald and Zucchini [8] show how a similar ‘hidden Markov’ model can be estimated from only one time series with many time points.

Some data have a strong measurement error component and other data clearly have heterogeneity in the inclination to change. If both are the case, it makes sense to set up a partially latent mover–stayer model, that is, to allow a certain proportion of perfectly measured stayers in the model, in addition to movers whose status was indirectly measured [4]. It is possible to estimate this model with data from four or more occasions. In fact, the example data for the latent Markov model of Table 3 were generated from a population that is a mixture of 75% stayers with 25% movers, only the latter responding with some measurement error. This means that model choice was not correct in the above example.

With real life data, model choice is not only a matter of making assumptions but also of testing whether the model fits the data. Computer programs like PanMark [10], WinLTA [14] and LEM [7] offer **maximum likelihood** (ML) estimation, that is, such parameters that make the data most likely, given the model. Then fit measures may be computed, most of which summarize the difference between fitted frequencies and observed frequencies. A plausible model may be selected on the basis of fit measures, but this is no guarantee for choosing the correct model. For valid model selection and for accurate parameter estimates, it is good to have rich data, for instance, with more than one indicator of the same latent concept at each occasion.

The models described so far are latent class models with specific Markovian restrictions. They offer a model-based extension to descriptive statistics. In some disciplines they are used for testing hypotheses, for instance, that learning goes through stages and that no one goes back to a lower stage. Collins and Wugalter [2] showed how a model for this theory should be built by setting some transition probabilities to zero, taking measurement error into account.

More restrictions can be tested when modeling joint and marginal distributions in one analysis. For instance, the hypothesis of no change in the marginal distribution, marginal homogeneity, can be tested in combination with a Markov chain [12]. In addition to marginal homogeneity, cross-tables of subsequent measurements can be tested for symmetry, or for quasi-symmetry if marginal homogeneity does not apply.

Once a model has been selected as an appropriate representation of reality, one may want to explain

its structure by relating latent classes to exogenous (predictor) variables. This can be done by considering the (posterior) distribution of latent classes for each response pattern. In the labor market example, for instance, one could have a latent distribution at the first occasion of 99.9% E, 0.05% U and 0.05% O for response pattern EEE, and so on, up to response pattern OOO. One can add up these distinct latent distributions to obtain the overall distribution of latent classes or, more usefully, to cross-tabulate some of the latent classes with exogenous variables [11]. After cross-tabulation, a logit analysis (*see Logistic Regression*) could follow. In this approach, parameter estimation of the latent Markov model precedes, and is independent of, the analysis with exogenous variables. Alternatively, full information ML approaches enable simultaneous estimation of all relevant parameters [3, 9] (*see Quasi-symmetry in Contingency Tables*).

With a cross-tabulation of increasingly many categorical variables, the number of cells eventually will be larger than the number of observations. Thus, sample tables are sparse, that is, many cells will be empty and therefore fit measures that follow a chi-square distribution for infinitely large samples are not applicable. In the context of latent Markov models, a **bootstrap** approach has been developed to find an appropriate distribution for these fit measures, which is implemented in PanMark and Latent Gold [5]. WinLTA uses a Gibbs sampling-based method to address the problem of sparse tables (*see Markov Chain Monte Carlo and Bayesian Statistics*).

Finally, it should be noted that the discrete time approach in this contribution is restrictive in the sense that information on events between panel measurement occasions is ignored. Usually, panel data do not have this sort of information. However, when information on the exact timing of events is somehow available, transition probabilities in discrete time can be exchanged for more basic flow parameters in continuous time, called *transition rates* or *hazard rates*, which apply in an infinitesimally small period of time. Relating these rates to exogenous variables is known as *event history analysis*, **survival analysis** or *duration analysis*.

Latent Variable

Many constructs that are of interest to social scientists cannot be observed directly. Examples are preferences, attitudes, behavioral intentions, and personality traits. Such constructs can only be measured indirectly by means of observable indicators, such as questionnaire items designed to elicit responses related to an attitude or preference. Various types of scaling techniques have been developed for deriving information on unobservable constructs of interest from the indicators. An important family of scaling methods is formed by latent variable models.

A latent variable model is a, possibly nonlinear, path analysis or graphical model (see **Path Analysis and Path Diagrams; Graphical Chain Models**). In addition to the manifest variables, the model includes one or more unobserved or latent variables representing the constructs of interest. Two assumptions define the causal mechanisms underlying the responses. First, it is assumed that the responses on the indicators are the result of an individual's position on the latent variable(s). The second assumption is that the manifest variables have nothing in common after controlling for the latent variable(s), which is often referred to as the *axiom of local independence*.

The two remaining assumptions concern the distributions of the latent and manifest variables. Depending on these assumptions, one obtains different kinds of latent variable models. According to Bartholomew (see [1, 3]), the four main kinds are factor analysis (FA), latent trait analysis (LTA), latent profile analysis (LPA), and **latent class analysis** (LCA) (see Table 1).

In FA and LTA, the latent variables are treated as continuous normally distributed variables. In LPA and LCA on the other hand, the latent variable is

discrete, and therefore assumed to come from a multinomial distribution. The manifest variables in FA and LPA are continuous. In most cases, their conditional distribution given the latent variables is assumed to be normal. In LTA and LCA, the indicators are dichotomous, ordinal, or nominal categorical variables, and their conditional distributions are assumed to be binomial or multinomial.

The more fundamental distinction in Bartholomew's typology is the one between continuous and discrete latent variables. A researcher has to decide whether it is more natural to treat the underlying latent variable(s) as continuous or discrete. However, as shown by Heinen [2], the distribution of a continuous latent variable model can be approximated by a discrete distribution. This shows that the distinction between continuous and discrete latent variables is less fundamental than one might initially think.

The distinction between models for continuous and discrete indicators turns out not to be fundamental at all. The specification of the conditional distributions of the indicators follows naturally from their scale types. The most recent development in latent variable modeling is to allow for a different distributional form for each indicator. These can, for example, be normal, student, lognormal, gamma, or exponential distributions for continuous variables, binomial for dichotomous variables, multinomial for ordinal and nominal variables, and Poisson, binomial, or negative-binomial for counts (see **Catalogue of Probability Density Functions**). Depending on whether the latent variable is treated as continuous or discrete, one obtains a generalized form of LTA or LCA.

Latin Squares Designs

Definition and History of Latin Squares

A Latin square has t rows, t columns, and t treatments. Each treatment appears once in every row and once in every column. See Jones and Kenward [13] and Kirk [14] for a description of how to construct and randomly select Latin squares of size t . Closely related magic squares may have appeared as early as 2200 B.C. [8]. Dürer's engraving 'Melancholia I' contained such a square in 1514 [9], and Arnaut Daniel, an eleventh-century troubador, employed a *sestina* form in poetry that persists to the present. Typically, the *sestina* has six six-line stanzas plus a three-line *semistanza* that is ignored here. The same six words are placed one at a time at the ends of lines with each stanza having each word once and the words being balanced across stanzas in Latin square fashion [2]. For further theory, history, and examples of *sestinas*, see [19, pp. 231–242]. In 1782, Euler examined Latin squares mathematically [20]. Fisher [7] first reported using Latin square designs in 1925 in his analyses of agricultural experiments.

Model of a Latin Square

Let the response in row i , column j , and treatment k be

$$Y_{ijk} = \mu + \alpha_i + \beta_j + \gamma_k + \lambda_{k'} + e_{ijk} \quad (1)$$

where α_i is the effect of row i , β_j is the effect of column j , γ_k is the effect of treatment k , $\lambda_{k'}$ is a carryover (residual) effect from the immediately prior treatment k' , and e_{ijk} is the random error for this response. Also assume that each e_{ijk} is i.i.d. $N(0, \sigma^2)$, that is, independently and identically normally distributed with mean zero and variance σ^2 . This model is called a **fixed effects model**.

To develop a mixed model (see **Linear Multi-level Models; Generalized Linear Mixed Models**), replace α_i with a random row effect, a_i , assumed to be i.i.d. $N(0, \sigma_a^2)$ and independent of the error scores. Some authors [4, 16] prefer **randomization tests** or resampling tests (also discussed in [13]) to mixed model analyses unless the persons studied were randomly selected from a specific population.

Behavioral scientists most frequently are interested in a repeated measurements Latin square with rows as persons, columns as periods (stages, trials, etc.), and Latin labels as treatments. For Period 1 with no prior treatments, $\lambda_{k'}$ is defined as 0. Equation (1) is called a *carryover model* (see **Carryover and Sequence Effects**); without $\lambda_{k'}$ it is the *classical Latin square model*. Notice, for example, for the classical model, that having every treatment once in every row and column implies that $\bar{Y}_A = \mu + \alpha_A + \bar{\beta} + \bar{\gamma} + \bar{e}_A$ and $\bar{Y}_B = \mu + \alpha_B + \bar{\beta} + \bar{\gamma} + \bar{e}_B$, making $\bar{Y}_A - \bar{Y}_B$ an unbiased estimate of the treatment effect difference $\alpha_A - \alpha_B$. *Warning: If interactions (see **Interaction Effects**) (not in Equation (1)) are present, a Latin square analysis is misleading.*

A Latin square design and a three-way factorial design both have three independent variables. Consider a 2 by 2 by 2 factorial design with factors A, B, and C. Such a design has eight cells: *A1B1C1*, *A1B1C2*, *A1B2C1*, *A1B2C2*, *A2B1C1*, *A2B1C2*, *A2B2C1*, and *A2B2C2*. When replicated, this design permits the assessment of three two-way interactions and one three-way interaction. However, one possible 2 by 2 Latin square for three variables only has four cells that correspond to the italicized cells above. Consequently, the difference in row means in this Latin square could be due to row effects, to the interaction between column and treatment effects, or to both. For other difficulties specific to 2 by 2 Latin squares, see [1, 10–12].

Analyzing a 4 by 4 Latin Square Data Set

Table 1 presents an efficient [2, pp. 185–188; 21, 22] Latin square design for carryover models, often termed a *Williams square*. The data in Table 1 come from a simulated experiment [2] on listener response to four different television episodes (treatments 1 through 4). The responses reported are applause-meter scores. Ordinarily, a conventional **analysis of variance** (ANOVA) for Latin square data yields the same results, regardless of whether persons are fixed or random effects. So, Table 2 summarizes just two (classical and carryover) ANOVAs for the data in Table 1. The classical analysis concludes that persons and treatments are significant ($p < 0.05$); the carryover analysis finds all four effects significant ($p < 0.001$). The latter

⁺ df_{Periods} drops to 2 with crossover analysis because of partial confounding of periods and carryover; df_{Error} becomes 3 because of the inclusion of carryover effects in the model.

conclusion is consistent with the simulated model parameters.

Expected Mean Squares and Procedures Related to Orthogonality and Other Design Features

In a Type I analysis (see **Type I, Type II and Type III Sums of Squares**) [18, Vol. 1, Ch. 9], one computes a sum of squares (*SS*) for the first effect, say persons, extracting all variability apparently associated with that effect. The next one extracts from the remaining *SS* a sum of squares for a second effect, reflecting any possible effect that remains. This continues until all sources of effects have been assessed. Nonorthogonal effects that result from a lack of balance of variables as in our carryover model lead to a contaminated Type I mean square for a variable that was extracted early. Thus, testing the persons effect first, then periods, treatments, and carryovers leads to [2, p. 181] $E(MS_{\text{Persons}}) = \sigma^2 + t\sigma_a^2 + Q(\text{Carryovers})$. Because $E(MS_{\text{Error}}) = \sigma^2$,

$F = MS_{\text{Persons}}/MS_{\text{Error}}$ has the *F* distribution only if $t\sigma_a^2 + Q(\text{Carryovers}) = 0$. This gives $E(MS_{\text{Persons}})$ the same value as $E(MS_{\text{Error}})$. A better option is to use a Type II analysis in which each sum of squares is what is left for one effect, given all other effects. Various sources, for example, [3, pp. 8–91] and [14, Ch. 8] provide formulas and programming procedures for a variety of statistical procedures for repeated measurement experiments such as that in Table 1. See [2, 6] for comparisons of BMDP, SAS, SPSS, and SYSTAT (see **Software for Statistical Analyses**) computer programs and analyses using the carryover model for data as in Table 1.

Analysis of Replicated Repeated Measurements Latin Square Data

See Edwards [5, pp. 372–381] for an example of a classical fixed-model analysis of a 5 by 5 Latin square experiment with five replications.

Jones and Kenward [13] reanalyzed a visual perception experiment [17] with 16 students such that two persons served in each row of an 8 by 8 Latin square for Periods 1 to 8 and also for Periods 9 to 16. They performed an extensive series of SAS PROC MIXED [15] carryover ANOVAs, some for complicated period effects and some with an antedependence correction for possible nonsphericity.

Laws of Large Numbers

Laws of large numbers concern the behavior of the average of n random variables, $S_n = 1/n \sum_{i=1}^n X_i$, as n grows large. This topic has an interesting early history dating back to the work of **Bernoulli** and **Poisson** in the eighteenth and nineteenth centuries; see [6] and [9] for details. For a fairly straightforward modern introduction, see [7]. There are two types of laws, namely, *weak* and *strong*, depending on the mode of convergence of the average S_n to its limit: *weak* refers to convergence in probability and *strong* denotes convergence with probability 1. The difference between these modes is perhaps best appreciated by those with a solid grounding in measure theory; see [3] or [8], for example. There are several versions of the law depending on assumptions regarding (a) the independence of the X_i , and (b) whether the X_i follow the same probability distribution. Here, we consider the simplest case in which the X_i are assumed to be mutually independent and follow the same probability distribution with finite mean μ [4, 8]. More general versions exist in which either, or both, of assumptions (a) and (b) are relaxed, but then, other conditions are imposed. For example: if the random variables have different means and different variances, but certain moment conditions hold, then the Kolmogorov strong law is obtained [8]; if the random variables form a stationary stochastic process (see **Markov Chains**), then a strong law is available (the ‘ergodic’ theorem, [1]); if both assumptions (a) and (b) are weakened while the random variables have a martingale structure (see **Martingales**), and a moment condition is satisfied, then a strong law is available [5, 8].

The weak law states that S_n converges in probability to μ as $n \rightarrow \infty$; put more precisely, this states that for any small positive number ϵ , $\Pr\{|S_n - \mu| < \epsilon\} \rightarrow 1$ as $n \rightarrow \infty$. The strong law states that S_n converges to μ with probability 1 as $n \rightarrow \infty$; put more precisely, this states that for any small positive number ϵ , $\lim_{n \rightarrow \infty} \Pr\{|S_n - \mu| < \epsilon\} = 1$. We now consider three applications of the law.

Application 1 The frequentist concept of probability is based on the notion of the stabilization of relative frequency (see **Probability: An Introduction**). Suppose that n independent experiments

are conducted under identical conditions, and suppose that, in each experiment, the event A either occurs, with probability π , or does not occur, with probability $1 - \pi$. In the i th experiment, let X_i take the value 1 if A occurs, and 0 if A does not occur ($i = 1, \dots, n$). Then S_n , the proportion of times that the event A occurs, is the relative frequency of the event A in the first n experiments and by the strong law, as $n \rightarrow \infty$, S_n converges with probability 1 to π , the true probability of the event A .

Application 2 Suppose that it is of interest to estimate the mean and variance of the reaction time in some large population of subjects, who are faced with a forced-choice perceptual task, and that reaction times are available from a simple random sample of n subjects from the population. Let X_i be a random variable representing the reaction time for the i th subject and suppose that the X_i have finite mean μ and variance σ^2 ($i = 1, \dots, n$). Consider the usual unbiased estimators S_n of μ and $T_n = n/(n - 1)\{1/n \sum_{i=1}^n X_i^2 - \bar{X}^2\}$ of σ^2 . Then, from the strong law, it follows that S_n converges with probability 1 to the population mean μ , that $1/n \sum_{i=1}^n X_i^2$ converges with probability 1 to the expectation of the X_i^2 (which is $\mu^2 + \sigma^2$), and, therefore, that T_n converges with probability 1 to the population variance σ^2 . These results provide theoretical support for the strong consistency of statistical estimation for the sample estimators S_n and T_n (see **Estimation**).

Application 3 We now illustrate how the law of large numbers provides theoretical support for the estimation of the P value associated with a Monte Carlo test. An experiment involving associative memory was conducted with a black-capped chickadee; see [2].

The bird was shown that there was food in a particular feeder and later had to find the food when presented with it and four other empty feeders. The baited feeder was determined randomly and the process was repeated 30 times. In the absence of learning, the order of the feeders that the bird looks in will be independent of where the food is, and so the bird is equally likely to find the food in the first, second, third, fourth, and fifth feeder it examines. The chickadee found the food 12 times in the first feeder it looked in, 8 times in the second, 5 times in the third, 5 times in the fourth and it never had to examine five feeders in order to get

2 Laws of Large Numbers

the food. Initially, it is of interest to test the null hypothesis that the chickadee is guessing randomly against the alternative hypothesis that this is not the case. Under the null hypothesis, no learning had occurred, and we would expect that the bird would find the food six times in each position, and one could calculate a chi-square test statistic to be 13. The P value associated with the test is the probability that the chi-squared test statistic takes a value of 13 or greater, assuming that the null hypothesis is true. Suppose now that n data sets of size 30 are generated assuming the null hypothesis to be true; that is, 1, 2, 3, 4, or 5 feeders are equally likely to be examined in any trial. Then, for each data set, the value of the chi-squared statistic is computed. Let X_i take the value 1, if the i th value of the test statistic is greater than or equal to 13, and 0 otherwise ($i = 1, \dots, n$). Then, S_n gives the proportion of times that the test statistic is greater than or equal to 13, given that the null hypothesis is true. By the strong law, S_n converges with probability 1 to the true P value associated with the test, and the estimate can be made as precise as required by generating the required number of data sets under the null hypothesis.

Least Squares Estimation

The method of least squares is about estimating parameters by minimizing the squared discrepancies between observed data, on the one hand, and their expected values on the other (see **Optimization Methods**). We will study the method in the context of a regression problem, where the variation in one variable, called the response variable Y , can be partly explained by the variation in the other variables, called covariables X (see **Multiple Linear Regression**). For example, variation in exam results Y are mainly caused by variation in abilities and diligence X of the students, or variation in survival times Y (see **Survival Analysis**) are primarily due to variations in environmental conditions X . Given the value of X , the best prediction of Y (in terms of mean square error – see **Estimation**) is the mean $f(X)$ of Y given X . We say that Y is a function of X plus noise:

$$Y = f(X) + \text{noise}.$$

The function f is called a regression function. It is to be estimated from sampling n covariables and their responses $(x_1, y_1), \dots, (x_n, y_n)$.

Suppose f is known up to a finite number $p \leq n$ of parameters $\beta = (\beta_1, \dots, \beta_p)'$, that is, $f = f_\beta$. We estimate β by the value $\hat{\beta}$ that gives the best fit to the data. The least squares estimator, denoted by $\hat{\beta}$, is that value of b that minimizes

$$\sum_{i=1}^n (y_i - f_\beta(x_i))^2, \quad (1)$$

over all possible b .

The least squares criterion is a computationally convenient measure of fit. It corresponds to **maximum likelihood estimation** when the noise is normally distributed with equal variances. Other measures of fit are sometimes used, for example, least absolute deviations, which is more robust against **outliers**. (See **Robust Testing Procedures**).

Linear Regression. Consider the case where f_β is a linear function of β , that is,

$$f_\beta(X) = X_1\beta_1 + \dots + X_p\beta_p. \quad (2)$$

Here $(X_1, \dots, X_p)$ stand for the observed variables used in $f_\beta(X)$.

To write down the least squares estimator for the linear regression model, it will be convenient to use matrix notation. Let $\mathbf{y} = (y_1, \dots, y_n)'$ and let $\mathbf{X}$ be the $n \times p$ data matrix of the n observations on the p variables

$$\mathbf{X} = \begin{pmatrix} \mathbf{x}_{1,1} & \dots & \mathbf{x}_{1,p} \\ \vdots & \dots & \vdots \\ \mathbf{x}_{n,1} & \dots & \mathbf{x}_{n,p} \end{pmatrix} = (\mathbf{x}_1 \dots \mathbf{x}_p), \quad (3)$$

where $\mathbf{x}_j$ is the column vector containing the n observations on variable j , $j = 1, \dots, p$. Denote the squared length of an n -dimensional vector $\mathbf{v}$ by $\|\mathbf{v}\|^2 = \mathbf{v}'\mathbf{v} = \sum_{i=1}^n v_i^2$. Then expression (1) can be written as

$$\|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2,$$

which is the squared distance between the vector $\mathbf{y}$ and the linear combination $\mathbf{b}$ of the columns of the matrix $\mathbf{X}$. The distance is minimized by taking the *projection* of $\mathbf{y}$ on the space spanned by the columns of $\mathbf{X}$ (see Figure 1).

Suppose now that $\mathbf{X}$ has full column rank, that is, no column in $\mathbf{X}$ can be written as a linear combination of the other columns. Then, the least squares estimator $\hat{\beta}$ is given by

$$\hat{\beta} = (\mathbf{X}'\mathbf{X})^{-1} \mathbf{X}'\mathbf{y}. \quad (4)$$

The Variance of the Least Squares Estimator.

In order to construct **confidence intervals** for the components of $\hat{\beta}$, or linear combinations of these components, one needs an estimator of the covariance

Figure 1 The projection of the vector $\mathbf{y}$ on the plane spanned by $\mathbf{X}$

2 Least Squares Estimation

matrix of $\hat{\beta}$. Now, it can be shown that, given $\mathbf{X}$, the covariance matrix of the estimator $\hat{\beta}$ is equal to

$$(\mathbf{X}'\mathbf{X})^{-1}\sigma^2,$$

where σ^2 is the variance of the noise. As an estimator of σ^2 , we take

$$\hat{\sigma}^2 = \frac{1}{n-p} \|\mathbf{y} - \mathbf{X}\hat{\beta}\|^2 = \frac{1}{n-p} \sum_{i=1}^n \hat{e}_i^2, \quad (5)$$

where the $\hat{e}_i$ are the residuals

$$\hat{e}_i = y_i - \mathbf{x}_{i,1}\hat{\beta}_1 - \cdots - \mathbf{x}_{i,p}\hat{\beta}_p. \quad (6)$$

The covariance matrix of $\hat{\beta}$ can, therefore, be estimated by

$$(\mathbf{X}'\mathbf{X})^{-1}\hat{\sigma}^2.$$

For example, the estimate of the variance of $\hat{\beta}_j$ is

$$\hat{\text{var}}(\hat{\beta}_j) = \tau_j^2 \hat{\sigma}^2,$$

where τ_j^2 is the j th element on the diagonal of $(\mathbf{X}'\mathbf{X})^{-1}$. A confidence interval for β_j is now obtained by taking the least squares estimator $\hat{\beta}_j \pm$ a margin:

$$\hat{\beta}_j \pm c\sqrt{\hat{\text{var}}(\hat{\beta}_j)}, \quad (7)$$

where c depends on the chosen confidence level. For a 95% confidence interval, the value $c = 1.96$ is a good approximation when n is large. For smaller values of n , one usually takes a more conservative c using the tables for the student distribution with $n - p$ degrees of freedom.

Numerical Example. Consider a regression with constant, linear and quadratic terms:

$$f_{\beta}(X) = \beta_1 + X\beta_2 + X^2\beta_3. \quad (8)$$

We take $n = 100$ and $x_i = i/n$, $i = 1, \dots, n$. The matrix $\mathbf{X}$ is now

$$\mathbf{X} = \begin{pmatrix} 1 & x_1 & x_1^2 \\ \vdots & \vdots & \vdots \\ 1 & x_n & x_n^2 \end{pmatrix}. \quad (9)$$

This gives

$$\mathbf{X}'\mathbf{X} = \begin{pmatrix} 100 & 50.5 & 33.8350 \\ 50.5 & 33.8350 & 25.5025 \\ 33.8350 & 25.5025 & 20.5033 \end{pmatrix},$$

$$(\mathbf{X}'\mathbf{X})^{-1} = \begin{pmatrix} 0.0937 & -0.3729 & 0.3092 \\ -0.3729 & 1.9571 & -1.8189 \\ 0.3092 & -1.8189 & 1.8009 \end{pmatrix}. \quad (10)$$

We simulated n independent standard normal random variables $e_1, \dots, e_n$, and calculated for $i = 1, \dots, n$,

$$y_i = 1 - 3x_i + e_i. \quad (11)$$

Thus, in this example, the parameters are

$$\begin{pmatrix} \beta_1 \\ \beta_2 \\ \beta_3 \end{pmatrix} = \begin{pmatrix} 1 \\ -3 \\ 0 \end{pmatrix}. \quad (12)$$

Moreover, $\sigma^2 = 1$. Because this is a simulation, these values are known.

To calculate the least squares estimator, we need the values of $\mathbf{X}'\mathbf{y}$, which, in this case, turn out to be

$$\mathbf{X}'\mathbf{y} = \begin{pmatrix} -64.2007 \\ -52.6743 \\ -42.2025 \end{pmatrix}. \quad (13)$$

The least squares estimate is thus

$$\hat{\beta} = \begin{pmatrix} 0.5778 \\ -2.3856 \\ -0.0446 \end{pmatrix}. \quad (14)$$

From the data, we also calculated the estimated variance of the noise, and found the value

$$\hat{\sigma}^2 = 0.883. \quad (15)$$

The data are represented in Figure 2. The dashed line is the true regression $f_{\beta}(x)$. The solid line is the estimated regression $f_{\hat{\beta}}(x)$.

The estimated regression is barely distinguishable from a straight line. Indeed, the value $\hat{\beta}_3 = -0.0446$ of the quadratic term is small. The estimated variance of $\hat{\beta}_3$ is

$$\hat{\text{var}}(\hat{\beta}_3) = 1.8009 \times 0.883 = 1.5902. \quad (16)$$

Using $c = 1.96$ in (7), we find the confidence interval

$$\beta_3 \in -0.0446 \pm 1.96\sqrt{1.5902} = [-2.5162, 2.470]. \quad (17)$$

Figure 2 Observed data, true regression (dashed line), and least squares estimate (solid line)

Thus, β_3 is not significantly different from zero at the 5% level, and, hence, we do not reject the hypothesis $H_0: \beta_3 = 0$.

Below, we will consider general test statistics for testing hypotheses on β . In this particular case, the test statistic takes the form

$$T^2 = \frac{\hat{\beta}_3^2}{\text{var}(\hat{\beta}_3)} = 0.0012. \quad (18)$$

Using this test statistic is equivalent to the above method based on the confidence interval. Indeed, as $T^2 < (1.96)^2$, we do not reject the hypothesis $H_0: \beta_3 = 0$.

Under the hypothesis $H_0: \beta_3 = 0$, we use the least squares estimator

$$\begin{pmatrix} \hat{\beta}_{1,0} \\ \hat{\beta}_{2,0} \end{pmatrix} = (\mathbf{X}_0' \mathbf{X}_0)^{-1} \mathbf{X}_0' \mathbf{y} = \begin{pmatrix} 0.5854 \\ -2.4306 \end{pmatrix}. \quad (19)$$

Here,

$$\mathbf{X}_0 = \begin{pmatrix} 1 & x_1 \\ \vdots & \vdots \\ 1 & x_n \end{pmatrix}. \quad (20)$$

It is important to note that setting β_3 to zero changes the values of the least squares estimates of β_1 and β_2 :

$$\begin{pmatrix} \hat{\beta}_{1,0} \\ \hat{\beta}_{2,0} \end{pmatrix} \neq \begin{pmatrix} \hat{\beta}_1 \\ \hat{\beta}_2 \end{pmatrix}. \quad (21)$$

This is because $\hat{\beta}_3$ is correlated with $\hat{\beta}_1$ and $\hat{\beta}_2$. One may verify that the correlation matrix of $\hat{\beta}$ is

$$\begin{pmatrix} 1 & -0.8708 & 0.7529 \\ -0.8708 & 1 & -0.9689 \\ 0.7529 & -0.9689 & 1 \end{pmatrix}.$$

Testing Linear Hypotheses. The testing problem considered in the numerical example is a special case of testing a linear hypothesis $H_0: A\beta = 0$, where A is some $r \times p$ matrix. As another example of such a hypothesis, suppose we want to test whether two coefficients are equal, say $H_0: \beta_1 = \beta_2$. This means there is one restriction $r = 1$, and we can take A as the $1 \times p$ row vector

$$A = (1, -1, 0, \dots, 0). \quad (22)$$

In general, we assume that there are no linear dependencies in the r restrictions $A\beta = 0$. To test the linear hypothesis, we use the statistic

$$T^2 = \frac{\|\mathbf{X}\hat{\beta}_0 - \mathbf{X}\hat{\beta}\|^2/r}{\hat{\sigma}^2}, \quad (23)$$

where $\hat{\beta}_0$ is the least squares estimator under $H_0: A\beta = 0$. In the numerical example, this statistic takes the form given in (18). When the noise is normally distributed, critical values can be found in a table for the F distribution with r and $n - p$ degrees of freedom. For large n , approximate critical values are in the table of the χ^2 distribution with r degrees of freedom.

Some Extensions

Weighted Least Squares. In many cases, the variance σ_i^2 of the noise at measurement i depends on x_i . Observations where σ_i^2 is large are less accurate, and, hence, should play a smaller role in the estimation of β . The *weighted* least squares estimator is that value of b that minimizes the criterion

$$\sum_{i=1}^n \frac{(y_i - f_b(x_i))^2}{\sigma_i^2}.$$

overall possible b . In the linear case, this criterion is numerically of the same form, as we can make the change of variables $\tilde{y}_i = y_i/\sigma_i$ and $\tilde{\mathbf{x}}_{i,j} = \mathbf{x}_{i,j}/\sigma_i$.

4 Least Squares Estimation

The minimum χ^2 -estimator (see **Estimation**) is an example of a weighted least squares estimator in the context of density estimation.

Nonlinear Regression. When f_β is a nonlinear function of β , one usually needs iterative algorithms to find the least squares estimator. The variance can then be approximated as in the linear case, with $\dot{f}_\beta(x_i)$ taking the role of the rows of $\mathbf{X}$. Here, $\dot{f}_\beta(x_i) = \partial f_\beta(x_i)/\partial \beta$ is the row vector of derivatives of $f_\beta(x_i)$. For more details, see e.g. [4].

Nonparametric Regression. In nonparametric regression, one only assumes a certain amount of smoothness for f (e.g., as in [1]), or alternatively, certain qualitative assumptions such as monotonicity (see [3]). Many nonparametric least squares procedures have been developed and their numerical and theoretical behavior discussed in literature. Related developments include estimation methods for models

where the number of parameters p is about as large as the number of observations n . The *curse of dimensionality* in such models is handled by applying various complexity regularization techniques (see e.g., [2]).

Leverage Plot

A residual versus leverage plot, or leverage plot for short, is a **scatterplot** of studentized **residuals** against hat values; the residuals are usually placed on the vertical axis. Its particular merit as a tool for regression diagnostics is in flagging up observations that are potentially high leverage points, regression **outliers**, and/or influential values (see **Multiple Linear Regression**).

In general, influential observations are both regression outliers and high leverage points, indicated by large studentized residuals and large hat values, respectively, and thus will appear in the top and bottom right corners of the plot. Observations that are regression outliers but not particularly influential will show up in the left corners, while cases having high leverage alone will tend to lie around the middle of the right margin.

In Figure 1, the observation, labeled A, toward the upper left corner of the plot (large studentized residual but fairly small hat value) is identified as a regression outlier though it is probably not especially influential. On the other hand, B in the bottom right corner (large studentized residual and large hat value) is likely to be an influential observation. The observation C which lies midway down the right margin of the plot (large hat value) is a high leverage point.

However, any cases picked out for attention in this informal way should be assessed in relation to all the data, as well as against more formal criteria. Further illustrations of simple leverage plots based on real-life data can be found in [2].

The simple plot described above can be enhanced by contours corresponding to various combinations of residual and hat value generating a constant value (usually the rule of thumb cut-off point) of

Figure 1 Leverage plot: Observation A shows up as a regression outlier, B as an influential observation, and C as a high leverage point

an influence measure such as DFITS. The contours allow the analyst to gauge the *relative* influence of observations (see, for example, [1]).

Another more sophisticated variant is based on a **bubble plot**. The studentized residuals and hat values are plotted in the usual way while the size of the circle used as the symbol is proportional to the value of the chosen influence measure for each observation.

Liability Threshold Models

Proposed by Pearson and Lee [5], the liability threshold model proposes that for dichotomous traits influenced by multiple factors of small effect, an underlying liability distribution exists. This population distribution of liability is assumed to be either normal or transformable to a normal distribution, with a mean of 0 and a variance of 1. On this liability distribution, there exists a threshold, t , above which all individuals exhibit the trait, and below which no individuals exhibit the trait (see Figure 1). An estimate of t can be estimated by determining the population frequency of the trait and inverting the normal distribution (also known as the *probit function*) with respect to the population frequency. Conceptually, this liability distribution reflects the biometrical model of quantitative genetics, with liability as the quantitative trait. Additionally, the model originates from the Pearson's formulation of the **tetrachoric correlation**.

This model can be extended to include multiple thresholds, when dealing with an ordered polychotomous variable (see Figure 1), such as categories including none, some, most, all or mild, moderate,

Figure 1 The two normal distributions represent the liability to develop the disorder. In the dichotomous case, t represents the threshold above which an individual will be come affected. In the polychotomous example, two thresholds exist, t_1 and t_2 . If an individual falls above t_1 and below t_2 , then he or she meets the criteria for mild affection status, whereas if an individual falls above t_2 , then he or she is severely affected

and severe diagnosis. The number of thresholds estimated by this model equals one less than the number of categories of the variable.

In practice, the liability threshold model is almost globally assumed for a genetic standpoint. In the context of **structural equation modelling** and the classical twin method (see **Twin Designs**), this model provides the backbone for the **maximum likelihood estimation** of ordinal data. Rather than estimate the means and variances of the traits, as is the case with continuous data, the thresholds for the liability distribution are estimated, while assuming that the distribution is normal, with a mean of 0 and a variance of 1. This approach is attractive when dealing with not only disease status, such as is the case with schizophrenia [2] or depression [1], but also when assessing measures such as neuroticism via the Eysenck Personality Questionnaire (EPQ) [4].

The same statistical procedures used to correct mean differences can be equally applied to thresholds. Conceptually, these procedures reflect mean shift in the liability distribution caused by a tractable factor, and act equally with respect to each threshold. For example, in the presence of an age effect, such that as age increases the threshold for affection decreases (e.g., Alzheimer's), an age regression on the single threshold can be applied.

One major issue with the liability threshold model for **2 x 2 tables** is that the model is fully specified. In the 2×2 table case, two thresholds and the correlation between the two assumed normal distributions are estimated. As the degrees of freedom for the model are defined by the number of elements in the table minus any constraints, in the case of the 2×2 table, we have 4 elements, but from a percentage perspective an element must be constrained because the proportion of the table sum to 1. Thus, we have 3 degrees of freedom, the same as the number of parameters, yielding a saturated model. So in the case of the 2×2 table, the liability threshold model represents a transformation of the data to a normal distribution rather than a model that can be tested. However, this issue is only relevant to the 2×2 case because with the increase in the number of categories of either of the variables comes an increase in the degrees of freedom, allowing for model testing, under the assumption of bivariate normal liability distribution [3]. In the case of univariate twin modelling, this

2 Liability Threshold Models

implies that the thresholds for twin 1 and twin 2 are equivalent for the single trait.

Linear Model

Although this term is used in a variety of contexts, its meaning is relatively simple. A linear model exists if the phenomenon in question can be accurately described with a ‘flat’ surface.

Consider a relationship between two variables A and C . If the surface that best describes this relationship is a straight line, then a linear model applies (Figure 1).

As can be seen in this **scatterplot**, the data points trend upward, and they do so in such a way that a straight line characterizes their ascent quite well.

Consider instead Figure 2.

Here, the linear model fits the data very poorly. This is reflected in the fact that the bivariate correlation between these two variables is zero. It is clear that there is a strong, but curvilinear, relationship between these two variables. This might be captured with the addition of an A -squared term to an equation that already contains A . This curvilinear model explains 56% of the variance in C , whereas the linear model (i.e., one that contains only A) explains none.

Figure 1 Scatterplot representing a linear bivariate relationship

Figure 2 Scatterplot representing a curvilinear bivariate relationship

If we were to create a **three dimensional scatterplot** of the relationship among two predictors, A and B , and a criterion C , the data might conform to any number of shapes. A cylindrical form trending upward and outward from the origin would suggest positive relationships between the predictors and the criterion. Because we have multiple predictors, the best-fitting surface is a plane rather than a line. In the cylindrical case, the best-fitting plane would bisect the cylinder lengthwise. If the best-fitting surface is a flat plane, then the data conform to a linear model. If instead a curved plane fits best, then the best-fitting model is curvilinear. This would be the case if the cylinder trended upward initially, but then headed downward. This would also be the case if A and B interact in their effect on C . In this latter case, the scatterplot would likely be saddle-shaped rather than cylindrical.

The issue becomes more complicated if we consider that many curvilinear models are ‘intrinsically linear’. A model is intrinsically linear if it can be represented as

$$\begin{aligned} f(Y) = & g_0(b_0) + b_1 g_1(X_1, \dots, X_j) \\ & + b_2 g_2(X_1, \dots, X_j) + \dots \\ & + b_k g_k(X_1, \dots, X_j) + h(e). \end{aligned} \quad (1)$$

Here we have a dependent variable (DV) Y and a set of predictors (X s). The model that captures the relationship between the predictors and the criterion is said to be intrinsically linear if some function of Y equals some function of the intercept plus a weight (b_1) times some function of the predictors plus another weight times some other function of the predictors, and so on, plus some function of error. Consider the curvilinear model presented earlier. We might test this relationship with the equation

$$C' = b_0 + b_1(A) + b_2(A^2) \quad (2)$$

where b_0 is the intercept, b_1 is expected to be zero because there is no overall upward or downward trend, and b_2 is expected to be large and negative because the slope of the line representing the AC relationship gets smaller as A increases. Although this model contain a nonlinear term (A^2), it is said to be intrinsically linear because C is estimated by an intercept, a weight times a function of the predictors ($1 * A$), and another weight times another function of the predictors ($A * A$). Another way of stating

2 Linear Model

this is that, although the surface of best fit for the relationship between A and C is distinctly nonlinear, the surface of best fit for the relationship between A , A^2 , and C is a flat plane.

Estimators such as ordinary least squares (OLS), require intrinsic linearity (*see* **Least Squares Estimation**). It is primarily for this reason that OLS regression cannot be used with dichotomous dependent

variables. It can be shown that the S-shaped surface that usually fits relationship involving dichotomous DVs best cannot be represented merely as weights time functions of predictors. The fact forms the basis of **logistic regression**, typically based on **maximum likelihood estimation**.

Linear Models: Permutation Methods

Permutation tests (*see* **Permutation Based Inference**) for the **linear model** have applications in behavioral studies when traditional parametric assumptions about the error term in a linear model are not tenable. Improved validity of Type I error rates can be achieved with properly constructed permutation tests. Perhaps more importantly, increased statistical **power**, improved robustness to effects of **outliers**, and detection of alternative distributional differences can be achieved by coupling permutation inference with alternative linear model estimators. For example, it is well-known that estimates of the mean in the linear model are extremely sensitive to even a single outlying value of the dependent variable compared to estimates of the median [7, 19]. Traditionally, linear modeling focused on estimating changes in the center of distributions (means or medians). However, quantile regression allows distributional changes to be estimated in all or any selected part of a distribution or responses, providing a more complete statistical picture that has relevance to many biological questions [6].

Parameters from the linear model in either its location, $\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$, or location scale, $\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\Gamma}\boldsymbol{\varepsilon}$, form can be tested with permutation arguments. Here, $\mathbf{y}$ is an $n \times 1$ vector of dependent responses, $\boldsymbol{\beta}$ is a $p \times 1$ vector of unknown regression parameters, $\mathbf{X}$ is an $n \times p$ matrix of predictors (with commonly the first column consisting of 1's for an intercept term), $\boldsymbol{\Gamma}$ is a diagonal $n \times n$ matrix where the n diagonal elements are the n corresponding ordered elements of the $n \times 1$ vector $\mathbf{X}\boldsymbol{\gamma}$ ($\text{diag}(\mathbf{X}\boldsymbol{\gamma})$), $\boldsymbol{\gamma}$ is a $p \times 1$ vector of unknown scale parameters, and $\boldsymbol{\varepsilon}$ is an $n \times 1$ vector of random errors that are independent and identically distributed (iid) with density $f_{\boldsymbol{\varepsilon}}$, distribution $F_{\boldsymbol{\varepsilon}}$, and quantile $F_{\boldsymbol{\varepsilon}}^{-1}$ functions. Various parametric regression models are possible, depending on which parameter of the error distribution is restricted to equal zero; for example, setting the expected value $F_{\boldsymbol{\varepsilon}}(\boldsymbol{\mu}|\mathbf{X}) = 0$ yields the familiar mean regression, setting any quantile $F_{\boldsymbol{\varepsilon}}^{-1}(\tau|\mathbf{X}) = 0$ yields quantile ($0 \leq \tau \leq 1$) regression, and the special case of $F_{\boldsymbol{\varepsilon}}^{-1}(0.5|\mathbf{X}) = 0$ yields median (least absolute deviation) regression [14]. The location

model with homoscedastic error variance is just a special case of the linear-location scale model when $\boldsymbol{\gamma} = (1, 0, \dots, 0)'$.

Estimates ($\hat{\boldsymbol{\beta}}$) of the various parametric linear models are obtained by minimizing appropriate loss functions of the residuals, $\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}$. Minimizing the sum of squared **residuals** yields the **least squares estimates** of the mean model. Minimizing the sum of asymmetrically weighted (τ for + residuals and $1 - \tau$ for - and 0 residuals) absolute values of the residuals yields the quantile regression estimates, where least absolute deviation regression for the median ($\tau = 0.5$) model being just a special case [15]. Consistent estimates with reduced sampling variation can be obtained for linear location-scale models by implementing weighted versions of the estimators, where weights are the reciprocal of the scale parameters, $\mathbf{W} = \boldsymbol{\Gamma}^{-1}$. In applications, the $p \times 1$ vector of scale parameters $\boldsymbol{\gamma}$ would usually have to be estimated. Weighted regression estimates are obtained by multiplying $\mathbf{y}$ and $\mathbf{X}$ by $\mathbf{W}$ and minimizing the appropriate function of the residuals as before. Examples of various estimates are shown in Figure 1.

Test Statistic

A drop in dispersion, F -ratio-like, test statistic that is capable of testing hypotheses for individual or multiple coefficients can be evaluated by similar permutation arguments for any of the linear model estimators above [2, 5, 7, 19]. This pivotal test statistic takes the form $T = (S_{\text{reduced}} \div S_{\text{full}}) - 1$, where S_{reduced} is the sum minimized by the chosen estimator for the reduced parameter model specified by the null hypothesis ($\mathbf{H}_0 : \boldsymbol{\beta}_2 = \boldsymbol{\xi}$) and S_{full} is the sum minimized for the full parameter model specified by the alternative hypothesis. This is equivalent to the usual F -ratio statistic for least squares regression but the degrees of freedom for reduced and full parameter models are deleted because they are not needed as they are invariant under the permutation arguments to follow. The reduced parameter model $\mathbf{y} - \mathbf{X}_2\boldsymbol{\xi} = \mathbf{X}_1\boldsymbol{\beta}_1 + \boldsymbol{\varepsilon}$ is constructed by partitioning $\mathbf{X} = (\mathbf{X}_1, \mathbf{X}_2)$, where $\mathbf{X}_1$ is $n \times (p - q)$ and $\mathbf{X}_2$ is $n \times q$; and by partitioning $\boldsymbol{\beta} = (\boldsymbol{\beta}_1, \boldsymbol{\beta}_2)$ where $\boldsymbol{\beta}_1$ is a $(p - q) \times 1$ vector of unknown nuisance parameters under the null and $\boldsymbol{\beta}_2$ is the $q \times 1$ vector of parameters specified by the null hypothesis $\mathbf{H}_0 : \boldsymbol{\beta}_2 = \boldsymbol{\xi}$

Figure 1 Lahontan cutthroat trout m^{-1} and width:depth ratios for small streams sampled 1993 to 1999 ($n = 71$) [10]; exponentiated estimates for 0.90, 0.50, and 0.10 regression quantiles and least squares (WLS) estimate for the weighted model $w(\ln y) = w(\beta_0 + \beta_1 X_1 + (\gamma_0 + \gamma_1 X_1)\epsilon)$, $w = (1.310 - 0.0017X_1)^{-1}$. Tabled values are estimates, 90% confidence intervals from inverting the permutation test, and estimated probabilities for $H_0: \beta_1 = 0$ based on the double permutation procedure for statistic T made with $m + 1 = 100000$ permutations

(frequently $\beta_2 = 0$). The unconstrained, full parameter model is $y = X_1\beta_1 + X_2\beta_2 + \epsilon$. To test hypotheses on weighted estimates in the linear location-scale model $y = X_1\beta_1 + X_2\beta_2 + \Gamma\epsilon$, the terms y , X_1 , and X_2 are replaced with their weighted counterparts Wy , WX_1 , and WX_2 , respectively, where W is the weights matrix, and the test statistic is constructed similarly. For homogeneous error models, $W = I$, where I is the $n \times n$ identity matrix.

When testing hypotheses on a single parameter, for example, $H_0: \beta_j = \xi_j$, the more general T statistic may be replaced with an equivalent t -ratio form $t = (\hat{\beta}_j - \xi_j) / \sqrt{S_{\text{full}}}$, where $\hat{\beta}_j$ is the full model estimate of β_j [1, 2, 18]. Use of test statistics that are not pivotal such as the actual parameter estimates is not recommended because they fail to maintain valid Type I error rates when there is multicollinearity (see

Collinearity) among the predictor variables in X [1, 2, 13].

Permutation Distribution of the Test Statistic

The test statistic for the observed data $T_{\text{obs}} = (S_{\text{reduced}} \div S_{\text{full}}) - 1$ is compared to a reference distribution of T formed by permutation arguments. The relevant exchangeable quantities under the null hypothesis to form a reference distribution are the errors ϵ from the null, reduced parameter model [1, 3, 17]. These can be permuted (shuffled) across the rows of X with equal probability. In general, the errors are unknown and unobservable. But, in the case of simultaneously testing all parameters other than the

intercept for the location model when $\mathbf{W} = \mathbf{I}$, $\mathbf{X}_1$ is an $n \times 1$ matrix of 1's, the residuals from the null, reduced parameter model $\mathbf{e}_{\text{red}} = \mathbf{y} - \mathbf{X}_1 \hat{\beta}_1$ or $\mathbf{y}$ differ from the errors $\boldsymbol{\varepsilon}$ by unknown constants that are invariant under permutation. Thus, in this case, a reference distribution for T can be constructed by either permuting $\mathbf{e}_{\text{red}}$ or $\mathbf{y}$ against the full model matrix $\mathbf{X}$ to yield probabilities under the null hypothesis (proportion of $T \geq T_{\text{obs}}$) that are exact, regardless of the unknown distribution of the errors [2, 5, 18]. The variables being tested in $\mathbf{X}_2$ may be continuous, indicators (1, 0, -1) for categorical groups, or both. Thus, exact probabilities for the null hypothesis are possible for the 1-way classification (ANOVA) (see **Analysis of Variance**) model for two or more treatment groups, for the single-slope parameter in a simple regression, and for all slope parameters simultaneously in a **multiple regression**. In practice, for reasonable n , a very large random sample of size m is taken from the $n!$ possible permutations so that probability under the null hypothesis is estimated by (the number of $T \geq T_{\text{obs}} + 1)/(m + 1)$. The error of estimating the P value by Monte Carlo resampling (see **Monte Carlo Simulation**) can be made arbitrarily small by using a large m , for example, $m + 1 \geq 10000$.

For null hypotheses on subsets of parameters from a linear model with multiple predictors, the reference distribution of T is approximated by permuting $\mathbf{e}_{\text{red}}$ against $\mathbf{X}$ [1, 2, 5, 7, 11, 21]. Permuting against the full model matrix $\mathbf{X}$ ensures that the correlation structure of the predictor variables is fixed, that is, the design is ancillary. As the residuals no longer differ from the errors $\boldsymbol{\varepsilon}$ by a constant, they are not exchangeable with equal probability and the resulting probability for the null hypothesis is no longer exact [1, 5, 9, 12]. Regardless, this permutation approach originally due to Freedman and Lane [11] was found to have perfect correlation asymptotically with the exact test for least squares regression (as if the errors $\boldsymbol{\varepsilon}$ were known) [3] and has performed well in simulations for least squares [2], least absolute deviation [7], and quantile regression [5]. Some authors have permuted $\mathbf{e}_{\text{full}} = \mathbf{y} - \mathbf{X} \hat{\beta}$ rather than $\mathbf{e}_{\text{red}}$ [1, 18, 21], but there is less theoretical justification for doing so, although it may yield similar results asymptotically for least squares regression estimates [2, 3]. There are alternative restricted permutation schemes that provide valid probabilities for linear models when the null hypothesis and hence $\mathbf{X}_2$ only

include indicator variables for categorical treatment groups [1, 4, 19, 20]. Permutation tests for random (see **Completely Randomized Design**) and mixed effects in multifactorial linear models (see **Linear Multilevel Models**) are discussed in [4].

There are several approaches to improving exchangeability of the residuals $\mathbf{e}_{\text{red}}$ under the null hypothesis to provide more valid Type I error rates. For the linear least squares regression estimator, linear **transformations** toward approximate exchangeability of the residuals from a model with $p - q$ parameters must reduce the dimension of $\mathbf{e}_{\text{red}}$ to $n - (p - q)$ or $n - (p - q) + 1$ and reduce $\mathbf{X}$ (or $\mathbf{WX}$) to conform, for example, by Gram-Schmidt orthogonalization [9]. This theory is not directly applicable to a nonlinear estimator like that used for quantile regression. But reducing the dimension of $\mathbf{e}_{\text{red}}$ by deleting $(p - q) - 1$ of the zero residuals and randomly deleting $(p - q) - 1$ rows of $\mathbf{X}$ to conform was found to improve Type I error rates for null hypotheses involving subsets of parameters for both linear location and location-scale quantile regression models with multiple independent variables [8]. This approach was motivated by [9] and the fact that quantile regression estimates for $p - q$ parameters must have at least $p - q$ zero residuals. An example of the Type I error rates for corrected and uncorrected residuals $\mathbf{e}_{\text{red}}$ for a 0.90 quantile regression model is shown in Figure 2. Another option for quantile regression is to use a τ -rank score procedure on $\mathbf{e}_{\text{red}}$, which transforms the $+$ residuals to τ , $-$ residuals to $\tau - 1$, and zero residuals to values in the interval $(\tau - 1, \tau)$, which are then used to compute a test statistic similar to the one above but based on a least squares (or weighted least squares) regression of the rank scores $\mathbf{r}$ on $\mathbf{X}$ [5]. This τ -rank score test can be evaluated by permuting $\mathbf{r}$ across the rows of $\mathbf{X}$ to yield a reference distribution to compute a probability under the null hypothesis. An example of the Type I error rates associated with this procedure also is shown in Figure 2.

An additional complication with permutation testing for the linear models occurs whenever the null model specified by the hypothesis does not include an intercept term so that the estimates are constrained through the origin. This includes testing a null hypothesis that includes the intercept term or when testing subsets of weighted parameter estimates for variables that are part of the weights function. Residuals from the estimates for the null, reduced parameter model $\mathbf{e}_{\text{red}}$ are no longer guaranteed to be

Figure 2 Cumulative distributions of 1000 estimated Type I errors for permutation tests of $H_0 : \beta_3 = \beta_5 = 0$ based on uncorrected permutation of raw residuals (solid line), deletion of $(p - q) - 1 = 3$ zero residuals (dashed line) prior to permutation, and by permuting τ -quantile rank scores (thick dotted line) for the 0.90 weighted quantile regression model $wy = w(\beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \beta_4 X_4 + \beta_5 X_3 X_4 + (1 + 0.05 X_1)\varepsilon)$; $X_1 = \text{Uniform}(0, 100)$, $X_2 = 4000 - 20X_1 + N(0, 300)$, $X_3 = 10 + 0.4X_1 + N(0, 16)$, X_4 is 0,1 indicator variable with half of n randomly assigned each, $\beta_0 = 36$, $\beta_1 = 0.10$, $\beta_2 = -0.005$, $\beta_4 = 2.0$, $\beta_3 = \beta_5 = 0$, ε is lognormal ($F_\varepsilon^{-1}(0.9) = 0$, $\sigma = 0.75$), $w = (1 + 0.05 X_1)^{-1}$, and $n = 90$. Each P value was estimated with $m + 1 = 10000$ permutations. Fine dotted 1:1 line is the expected cdf

centered on their appropriate distributional parameter, for example, $F_e(\bar{x}|\mathbf{X}_1) \neq 0$, although $F_e(\mu|\mathbf{X}_1) = 0$. Instead, the estimated distributional parameter associated with 0 for $\mathbf{e}_{\text{red}}$ has random binomial sampling variation that needs to be incorporated into the permutation scheme to provide valid Type I error rates. A double permutation scheme has been proposed for providing valid Type I errors for these hypotheses [5, 8, 16]. The first step uses a random binomial variable, $\tau^* \sim \text{binomial}(\tau, n)$, to determine the value on which the residuals $\mathbf{e}_{\text{red}}$ are centered, $\mathbf{e}_{\text{red}}^* = \mathbf{e}_{\text{red}} - F_e^{-1}(\tau^*|\mathbf{X}_1)$, and the second step permutes the randomly centered residuals $\mathbf{e}_{\text{red}}^*$ to the matrix $\mathbf{X}$. For least squares regression, τ is taken as 0.5. An example of Type I error rates for the double permutation compared to the uncorrected standard permutation test for the hypothesis $H_0 : \beta_0 = 0$ for a 0.5 quantile regression model is shown in Figure 3.

Figure 3 Cumulative distributions of 1000 estimated Type I errors for permutation tests of $H_0 : \beta_0 = 0$ based on uncorrected permutation of raw residuals (solid line) and double permutation of residuals (dashed line) for the 0.50 quantile regression model $y = \beta_0 + \beta_1 X_1 + \varepsilon$; $X_1 = \text{Uniform}(0, 100)$, $\beta_0 = 0$, $\beta_1 = 0.10$, ε is lognormal ($F_\varepsilon^{-1}(0.5) = 0$, $\sigma = 0.75$), and $n = 150$. Each P value was estimated with $m + 1 = 10000$ permutations. Fine dotted 1:1 line is the expected cdf

Example Application

In applications, we often make use of the fact that confidence intervals on parameters in a linear model may be constructed by inversion of permutation tests [5, 7, 18]. We obtain a $(1 - \alpha) \times 100\%$ confidence interval on a single parameter for a variable $\mathbf{x}_2 = \mathbf{X}_2$ by making the transformation $\mathbf{y} - \mathbf{x}_2 \xi$ on a sequence of values of ξ and collecting those values that have $P \geq \alpha$ for a test of the null hypothesis $H_0 : \beta_2 = \xi$.

The data in Figure 1 were from a study designed to evaluate changes in Lahontan cutthroat trout (*Oncorhynchus clarki henshawi*) densities as a function of stream channel morphology as it varies over the semidesert Lahontan basin of northern Nevada, USA [10]. The quantile regression analyses published in [10] used inferential procedures based on asymptotic distributional evaluations of the τ -quantile rank score statistic. Here, for a selected subset of quantiles, the 90% confidence intervals and hypothesis of zero slope were made with permutation tests based on the T statistic and permuting residuals $\mathbf{e}_{\text{red}}$. Because

the null model for the weighted estimates was implicitly forced through the origin, the double permutation scheme was required to provide valid Type I error rates. It is obvious in this location-scale model that restricting estimation and inferences to central distributional parameters, whether the mean or median, would have failed to detect changes in the trout densities at lower and higher portions of the distribution. Note that the permutation-based 90% confidence intervals for the weighted least squares estimate do not differ appreciably from the usual F distribution evaluation of the statistic nor do the intervals for the quantile estimates differ much from those based on the quantile rank score inversion [6].

Software

Computer routines for performing permutation tests on linear, least squares regression models are available in the Blossom software available from the U. S. Geological Survey (www.fort.usgs.gov/products/software/software.asp), in RT available from Western EcoSystems Technology, Inc. (www.west-inc.com/), in NPMANOVA from the web page of M. J. Anderson (www.stat.auckland.ac.nz/~mja/), and from the web page of P. Legendre (www.fas.umontreal.ca/BIOL/legendre/). The Blossom software package also features permutation tests for median and quantile regression. General permutation routines that can be customized for testing linear models are available in S-Plus and R.

Linear Multilevel Models

Hierarchical Data

Data are often hierarchical (*see* **Hierarchical Models**). By this we mean that data contain information about observation units at various levels, where the lower-level units are nested within the higher-level units. Some examples may clarify this. In repeated measurement or growth curve data (*see* **Repeated Measures Analysis of Variance; Growth Curve Modeling**), we have several observations in time on each of a number of different individuals. The time points are the lowest level and individuals are the higher level. In school effectiveness studies we have observations on students (the lowest or first level), on the schools in which these students are enrolled (the second level), and maybe even on school districts these schools are in (a third level).

Once we have data on various levels, we have to decide at which level to analyze. We can aggregate student variables to the school level or disaggregate school variables to the student level. In the first case, we lose potentially large amounts of useful information, because information about individual students disappears from the analysis. In the second case, we artificially create dependencies in the data, because students in the same school by definition get the same score on a disaggregated school variable.

Another alternative is to do a separate analysis for each higher-level unit. For example, we do a student-level regression analysis for each school separately. This, however, tends to introduce a very large number of parameters. It also ignores the fact that it makes sense to assume the different analyses will be related, because all schools are functioning within the same education system.

Multilevel models combine information about variables at different levels in a single model, without aggregating or disaggregating. It provides more data reduction than a separate analysis for each higher-level unit, and it models the dependency between lower-level units in a natural way. Multilevel models originated in school effectiveness research, and the main textbooks discussing this class of techniques still have a strong emphasis on educational applications [5, 13]. But hierarchical data occur in many disciplines, so there are now applications in

the health sciences, in biology, in sociology, and in economics.

Linear Multilevel Model

A linear multilevel model, in the two-level case, is a regression model specified in two stages, corresponding with the two levels. We start with separate linear regression models for each higher-level unit, specified as

$$\underline{y}_j = X_j \underline{\beta}_j + \underline{\epsilon}_j. \quad (1a)$$

Higher level units (schools) are indexed by j , and there are m of them. Unit j contains n_j observations (students), and thus the outcomes $\underline{y}_j$ and the error terms $\underline{\epsilon}_j$ are vectors with n_j elements. The predictors for unit j are collected in an $n_j \times p$ matrix X_j .

In our model specification random variables, and random vectors, are underlined. This shows clearly how our model differs from classical separate linear regression models, in which the regression coefficients β_j are nonrandom. This means, in the standard frequentist interpretation, that if we were to replicate our experiment then in the classical case all replications have the same regression coefficients, while in our model the random regression coefficients would vary because they would be independent realizations of the same random vector $\underline{\beta}_j$. The differences are even more pronounced, because we also use a second-level regression model, which has the first-level regression coefficients as outcomes. This uses a second set of q regressors, at the second level. The submodel is

$$\underline{\beta}_j = Z_j \gamma + \underline{\delta}_j, \quad (1b)$$

where the Z_j are now $p \times q$ and γ is a fixed set of q regression coefficients that all second level units have in common.

In our regression model, we have not underlined the predictors in X_j and Z_j , which means we think of them as fixed values. They are either fixed by design, which is quite uncommon in social and behavioral sciences, or they are fixed by the somewhat artificial device of conditioning on the values of the predictors. In the last case, the predictors are really random variables, but we are only interested in what happens if these variables are set to their observed values.

2 Linear Multilevel Models

We can combine the specifications in (1a) and (1b) to obtain the linear mixed model

$$\underline{y}_j = X_j Z_j \gamma + X_j \underline{\delta}_j + \underline{\epsilon}_j. \quad (2)$$

This model has both fixed regression coefficients γ and random regression coefficients $\underline{\delta}_j$. In most applications, we suppose that both regressions have an intercept, which means that all X_j and all Z_j have a column with elements equal to one.

For the error terms $\underline{\delta}_j$ and $\underline{\epsilon}_j$ in the two parts of the regression model, we make the usual strong assumptions. Both have expectation zero, they are uncorrelated with each other within the same second-level unit, and they are uncorrelated between different second-level units. We also assume that first-level disturbances are homoscedastic, and that both errors have the same variance-covariance matrix in all second-level units. Thus, $V(\underline{\epsilon}_j) = \sigma^2 I$ and we write $V(\underline{\delta}_j) = \Omega$. This implies that

$$E(\underline{y}_j) = X_j Z_j \gamma, \quad (3a)$$

$$V(\underline{y}_j) = X_j \Omega X_j' + \sigma^2 I. \quad (3b)$$

Thus, we can also understand mixed linear models as heteroscedastic regression models with a specific interactive structure for the expectations and a special **factor analysis** structure for the covariance matrix of the disturbances. Observations in the same two-level unit are correlated, and thus we have correlations between students in the same school and between observations within the same individual at different time-points. We also see the correlation is related to the similarity in first-level predictor values of units i and k . Students with similar predictor values in X_j will have a higher correlation.

To explain more precisely how the $n_j \times q$ design matrices $U_j = X_j Z_j$ for the fixed effects usually look, we assume that Z_j has the form

$$Z_j = \begin{bmatrix} h_j' & 0 & \cdots & 0 \\ 0 & h_j' & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & h_j' \end{bmatrix}, \quad (4)$$

where h_j is a vector with r predictor values for second-level unit j . Thus, $q = pr$, and $\underline{\beta}_{js} = h_j' \gamma_s + \underline{\delta}_{js}$. With this choice of Z_j , which is the usual one in multilevel models, the matrix U_j is of the form

$$U_j = [x_{j1} h_j' | \cdots | x_{jp} h_j'], \quad (5)$$

that is, each column of U is the product of a first-level predictor and a second-level predictor. All $p \times r$ cross-level interactions get their own column in U . If the X_j have their first column equal to one, and the h_j have their first element equal to one, then it follows that the columns of X_j themselves and the (disaggregated) columns of H are among the pq interactions.

In the balanced case of the multilevel model, all second-level units j have the same $n \times p$ matrix of predictors X . This happens, for example, in growth curve models, in which X contains the same fixed functions (orthogonal polynomials, for instance) of time. In the balanced case, we can collect our various observations and parameters in matrices, and write $\underline{Y} = \underline{B} X' + \underline{E}$ and $\underline{B} = Z \Gamma + \underline{\Delta}$ or $\underline{Y} = Z \Gamma X' + \underline{\Delta} X' + \underline{E}$. Here the outcomes $\underline{Y}$ are in a matrix of order $m \times n$, individuals by time points, and the fixed parameters are in a $q \times p$ matrix Γ . This shows, following Stenio et al. [17], how multilevel ideas can be used to generalize the basic **growth curve model** of Pothoff and Roy [12].

Parameter Constraints

If p and q , the number of predictors at both levels, are at all large, then obviously their product pq will be very large. Thus, we will have a linear model with a very large number of regression coefficients, and in addition to the usual residual variance parameter σ^2 we will also have to estimate the $1/2p(p+1)$ parameters in Ω . The problem of having too many parameters for fast and stable estimation is compounded by the fact that the interactions in U will generally be highly correlated, and that consequently the regression problem is ill-conditioned. This is illustrated forcefully by the relatively small examples in Kreft and De Leeuw [7].

The common procedure in multilevel analysis to deal with the large number of parameters is the same as in other forms of regression analysis. Free parameters are set equal to zero, or, to put it differently, we use variable selection procedures. Setting regression coefficients (values of γ) equal to zero is straightforward, because it simply means that cross-level interactions are eliminated from the model. Nevertheless, the usual variable selection problem applies, if we have pq variables to include

or exclude, we can make 2^{pq} possible model choices and for large pq there is no optimal way to make such a choice. It is argued forcefully in [7] that either multilevel modeling should be limited to situations with a small numbers of variables or it should only be applied in areas in which there is sufficient scientific theory on the basis of which to choose predictors.

Another aspect of variable selection is that we can set some of the random coefficients in $\underline{\delta}_j$ to zero. Thus, the corresponding predictor in X only has a fixed effect, not a random effect. This means that particular row and column of Ω corresponding with that predictor are set to zero. It is frequently useful to use this strategy in a rather extreme way and set the random parts of all regression coefficients, except the intercept, equal to zero. This leads to random intercept models, which have far fewer parameters and are much better conditioned. They are treated in detail in Longford [10].

If we set parts on Ω to zero, we must be careful. In Kreft et al. [8] it is shown that requiring Ω to be diagonal, for instance, destroys the invariance of the results under centering of the variables. Thus, in a model of this form, we need meaningful zero points for the variables, and meaningful zero points are quite rare in social and behavioral applications (see **Centering in Linear Multilevel Models**).

Generalizations

The linear multilevel model can be, and has been, generalized in many different directions. It is based on many highly restrictive assumptions, and by relaxing some or all of these assumptions we get various generalizations.

First, we can relax the interaction structure of $U_j = X_j Z_j$ and look at the multilevel model for general $n_j \times q$ design matrices U_j . Thus, we consider more general models in which some of the predictors have fixed coefficients and some of the predictors have random coefficients. We can write such models, in the two-level case, simply as

$$\underline{y}_j = U_j \beta_j + X_j \underline{\delta}_j + \underline{\epsilon}_j. \quad (6)$$

It is possible, in fact, that there is overlap in the two sets of predictors U_j and X_j , which means that regressions coefficients have both a fixed part and a

random part. Second, we can relax the homoscedasticity assumptions $V(\underline{\epsilon}_j) = \sigma^2 I$. We can introduce σ_j^2 , so that the error variance is different for different second-level units. Or we can allow for more general parametric error structures $V(\underline{\epsilon}_j) = \Sigma_j(\theta)$, for example, by allowing auto-correlation between errors at different time points within the same individual (see **Heteroscedasticity and Complex Variation**).

Third, it is comparatively straightforward to generalize the model to more than two levels. The notation can become somewhat tedious, but when all the necessary substitutions have been made we still have a linear mixed model with nested random effects, and the estimation and data analysis proceed in the same way as in the two-level model.

Fourth, the device of modeling parameter vectors as random is strongly reminiscent of the Bayesian approach to statistics (see **Bayesian Statistics**). The main difference is that in our approach to multilevel analysis we still have the fixed parameters γ , σ^2 and Ω that must be estimated. In a fully Bayesian approach one would replace these fixed parameters by random variables with some prior distribution and one can then compute the posterior distribution of the parameters vectors, which are now all random effects. The Bayesian approach to multilevel modeling (or hierarchical linear modeling) has been explored in many recent publications, especially since the powerful **Markov Chain Monte Carlo** tools became available.

Fifth, we can drop the assumption of linearity and consider nonlinear multilevel models or generalized linear multilevel models (see **Nonlinear Mixed Effects Models; Generalized Linear Mixed Models**). Both are discussed in detail in the basic treatises of Raudenbush and Bryk [13] and Goldstein [5], but discussing them here would take us too far astray. The same is true for models with multivariate outcomes, in which the elements of the vector y_j are themselves vectors, or even matrices. A recent application of multilevel models in this context is analysis of fMRI data [2].

And finally, we can move multilevel analysis from the regression context to the more general framework of latent variable modeling. This leads to multilevel factor analysis and to various multilevel structural equation models. A very complete treatment of current research in that field is in Skrondal and Rabe-Hesketh [16].

Estimation

There is a voluminous literature on estimating multi-level models, or, more generally, mixed linear models [15]. Most methods are based on assuming normality of the random effects and then using **maximum likelihood estimation**. The likelihood function depends on the regression coefficients for the fixed variables and the variances and covariances of the random effects. It is easily minimized, for instance, by alternating minimization over γ for fixed σ^2 and Ω , and then minimization over σ^2 and Ω for fixed γ , until convergence. This is sometimes known as or Iterative Generalized Least Squares IGLS, [4]. It is also possible to treat the random coefficients as missing data and apply the EM algorithm [13] (see **Maximum Likelihood Estimation**), or to apply Newton's method or Fisher Scoring to optimize the likelihood [3, 9] (see **Optimization Methods**).

There is more than one likelihood function we can use. In the early work, the likelihood of the observations was used; later on this was largely replaced by using the likelihood of the least squares residuals. The likelihood of the observations is a function of σ^2 , Ω and γ . The disadvantage of the FIML estimates obtained by maximizing this full information likelihood function is that variance components tend to be biased, in the same way, and for the same reason, why the maximum likelihood of the sample variance is biased. In the case of the sample variance, we correct for the bias of the estimate by maximizing the likelihood of the deviations of the sample mean. In the same way, we can study the likelihood of a set of linear combinations of the observations, where the coefficients of the linear combinations are chosen orthogonal to the X_j . This means that γ disappears from the residual or reduced likelihood, which is now only a function of the variance and covariance components. The resulting REML estimates, originally due to Patterson and Thomson [11], can be computed with small variations of the more classical maximum likelihood algorithms (IGLS, EM, Scoring), because the two types of likelihood functions are closely related.

Of course REML does not give an estimate of the fixed regression coefficients, because the residual likelihood does not depend on γ . This problem is resolved by estimating γ by generalized least squares, using the REML estimates of the variance components. Neither REML nor FIML gives estimates of

the random regression coefficients or random effects. Random variables are not fixed parameters, and consequently they cannot be estimated in the classical sense. What we can estimate is the conditional expectation of the random effects given the data. These conditional expectations can be estimated by plug-in estimates using the REML or FIML estimates of the fixed parameters. They are also known as the *best linear unbiased predictors*, the *empirical Bayes estimates*, or the BLUP's [14] (see **Random Effects in Multivariate Linear Models: Prediction**).

There is a large number of software packages designed specifically for linear multilevel models, although most of them by now also incorporate the generalizations we have discussed in the previous section. The two most popular special purpose packages are HLM, used in Raudenbush and Bryk [13], and MLWin, used in Goldstein [5]. Many of the standard statistical packages, such as SAS, SPSS, Stata, and R now also have multilevel extensions written in their interpreted matrix languages (see **Software for Statistical Analyses**).

School Effectiveness Example

We use school examination data previously analyzed with multilevel methods by Goldstein et al. [6]. Data are collected on 4059 students in 65 schools in Inner London. For each student, we have a normalized exam score (`normexam`) as the outcome variable. Student-level predictors are gender (coded as a dummy `genderM`) and standardized London Reading Test score (`standlrt`). The single school-level predictors we use is school gender (mixed, boys, or girls school, abbreviated as `schgend`). This is a categorical variable, which we code using a boyschool-dummy `schgendboys` and a girlschool-dummy `schgendgirls`.

Our first model is a simple random intercept model, with a single variance component. Only the intercept is random, all other regression coefficients are fixed. The model is

$$\begin{aligned} \text{normexam}_{ij} &= \alpha_j + \text{standlrt}_{ij}\beta_1 \\ &\quad + \text{gender}_{ij}\beta_2 + \epsilon_{ij}, \\ \alpha_j &= \text{schgendboys}_j\gamma_1 \\ &\quad + \text{schgendgirls}_j\gamma_2 + \delta_j \quad (7) \end{aligned}$$

Table 1 Estimates school effectiveness example

source	Random Model	Fixed Model
intercept	−0.00 (0.056)	−0.03 (0.025)
standlrt	0.56 (0.012)	0.56 (0.017)
genderM	−0.17 (0.034)	−0.17 (0.034)
schgendboys	0.18 (0.113)	0.18 (0.043)
schgendgirls	0.16 (0.089)	0.17 (0.033)
ω^2	0.086	—
σ^2	0.563	0.635
ρ	0.132	—

We compare this with the model without a random intercept δ_j .

REML estimation of both models gives the following table of estimates, with standard errors in parentheses. In Table 1 we use ω^2 for the variance of the random intercept, the single element of the matrix Ω in this case.

This is a small example, but it illustrates some basic points. The estimated intraclass correlation ρ is only 0.132 in this case, but the fact that it is nonzero has important consequences. We see that if the random coefficient model holds then the standard errors of the regression coefficient from the fixed model are far too small. In fact, in the fixed model the school variables `schgendboys` and `schgendgirls` are highly significant, while they are not even significant at the 5% level in the random model. We also see that the estimate of σ^2 is higher in the fixed model, which is not surprising because the random model allows for an additional parameter to model the variation. Another important point is that the actual values of the regression coefficients in the fixed and random model are very close. Again, this is not that surprising, because after all in REML the fixed coefficients are estimated with least squares methods as well.

Growth Curve Example

We illustrate repeated measure examples with a small dataset taken from the classical paper by Pothoff and Roy [12]. Distances between pituitary gland and pterygomaxillary fissure were measured using x-rays in $n = 27$ children (16 males and 11 females) at $m = 4$ time points, at ages 8, 10, 12, and 14. Data can be collected in a $n \times m$ matrix Y . We also use a $m \times p$

matrix X of the first $p = 2$ orthogonal polynomials on the m time points.

The first class of models we consider is $\underline{Y} = B\underline{X}' + \underline{E}$ with B a $n \times p$ matrix of regression coefficients, one for each subject, and with $\underline{E}$ the $n \times m$ matrix of disturbances. We suppose the rows of $\underline{E}$ are independent, identically distributed centered normal vectors, with dispersion Σ . Observe that the model here tells us the growth curves are straight lines, not that the deviations from the average growth curves are on a straight line (see **Growth Curve Modeling**).

Within this class of models we can specify various submodels. The most common one supposes that $\Sigma = \sigma^2 I$. Using the orthogonality of the polynomials in X , we find that in this case the regression coefficients are estimated simply by $\hat{B} = YX$. But many other specifications are possible. We can, on the one hand, require Σ to be a scalar, diagonal, or free matrix. And we can, on the other hand, require the regression coefficients to be all the same, the same for all boys and the same for all girls, or free (all different). These are all fixed regression models. The minimum deviances (minus two times the maximized likelihood) are shown in the first three rows of Table 2. In some combinations there are too many parameters. As in other linear models this means the likelihood is unbounded above and the maximum likelihood estimate does not exist [1].

We show the results for the simplest case, with the regression coefficients ‘free’ and the dispersion matrix ‘scalar’. The estimated growth curves are in Figure 1. Boys are solid lines, girls are dashed. The estimated σ^2 is 0.85.

We also give the results for the ‘gender’ regression coefficients and the ‘free’ dispersion matrix. The two regression lines are in Figure 2. The regression line for boys is both higher and steeper than the one for girls. There is much less room in this model to incorporate the variation in the data using the regression coefficients, and thus we expect the

Table 2 Mixed model fit

	B equal	B gender	B free
Σ scalar	307(3)	280(5)	91(55)
Σ diagonal	305(6)	279(8)	−∞(58)
Σ free	233(12)	221(14)	−∞(64)
random	240(6)	229(8)	−∞(58)

Figure 1 Growth curves for the free/scalar model

Figure 2 Growth curves for the gender/free model

Table 3 Σ from gender/free model				
	8	10	12	14
Correlations	1.00			
	0.54	1.00		
	0.65	0.56	1.00	
	0.52	0.72	0.73	1.00
Variances	5.12	3.93	5.98	4.62

estimate of the residual variance to be larger. In Table 3 we give the variances and correlations from

the estimated Σ . The estimated correlations between the errors are clearly substantial.

The general problem with fixed effects models in this context is clear from both the figures and the tables. To make models realistic we need a lot of parameters, but if there are many parameters we cannot expect the estimates to be very good. In fact in some cases we have unbounded likelihoods and the estimates we look for do not even exist. Also, it is difficult to make sense of so many parameters at the same time, as Figure 1 shows.

Next consider random coefficient models of the form $\underline{Y} = \underline{B}X' + \underline{E}$, where the rows of $\underline{B}$ are uncorrelated with each other and with all of $\underline{E}$. By writing $\underline{B} = B + \underline{\Delta}$ with $B = E(\underline{B})$ we see that we have a mixed linear model of the form $\underline{Y} = BX' + \underline{\Delta}X' + \underline{E}$. Use Ω for the dispersion of the rows of $\underline{\Delta}$. It seems that we have made our problems actually worse by introducing more parameters. But allowing random variation in the regression coefficients makes the restrictive models for the fixed part more sensible. We fit the ‘equal’ and ‘gender’ versions for the regression coefficients B , together with the ‘scalar’ version of Σ , leaving Ω ‘free’.

Deviances for the random coefficient model are shown in the last row of Table 2. We see a good fit, with a relatively small number of parameters. To get growth curves for the individuals we compute the BLUP, or conditional expectation, $E(\underline{B}|Y)$, which

Figure 3 Growth curves for the mixed gender model

turns out to be

$$\begin{aligned} E(\underline{B}|Y) &= \tilde{B}[I - \Omega(\Omega + \sigma^2 I)^{-1}] \\ &\quad + \hat{B}\Omega(\Omega + \sigma^2 I)^{-1}, \end{aligned} \quad (8)$$

where $\tilde{B}$ is the mixed model estimate and $\hat{B} = YX$ is the least squares estimate portrayed in Figure 1. Using the ‘gender’ restriction on the regression coefficients the conditional expectations are plotted in Figure 3.

We see they provide a compromise solution, that shrinks the ordinary least squares estimates in the direction of the ‘gender’ mixed model estimates. We more clearly see the variation of the growth curves for the two genders around the mean gender curve. The estimated σ^2 for this model is 1.72.

Linear Statistical Models for Causation: A Critical Review

Introduction

Regression models are often used to infer causation from association. For instance, Yule [79] showed – or tried to show – that welfare was a cause of poverty. Path models and structural equation models are later refinements of the technique. Besides Yule, examples to be discussed here include Blau and Duncan [12] on stratification, as well as Gibson [28] on the causes of McCarthyism. Strong assumptions are required to infer causation from association by modeling. The assumptions are of two kinds: (a) causal, and (b) statistical. These assumptions will be formulated explicitly, with the help of response schedules in hypothetical experiments. In particular, parameters and error distributions must be stable under intervention. That will be hard to demonstrate in observational settings. Statistical conditions (like independence) are also problematic, and latent variables create further complexities. Causal modeling with path diagrams will be the primary topic. The issues are not simple, so examining them from several perspectives may be helpful. The article ends with a review of the literature and a summary.

Regression Models in Social Science

Legendre [49] and Gauss [27] developed regression to fit data on orbits of astronomical objects. The relevant variables were known from Newtonian mechanics, and so were the functional forms of the equations connecting them. Measurement could be done with great precision, and much was known about the nature of errors in the measurements and in the equations. Furthermore, there was ample opportunity for comparing predictions to reality. By the turn of the century, investigators were using regression on social science data where such conditions did not hold, even to a rough approximation. **Yule** [79] was a pioneer. At the time, paupers in England were supported either inside grim Victorian institutions called *poor-houses* or outside, according to decisions made by

local authorities. Did policy choices affect the number of paupers? To study this question, Yule proposed a regression equation,

$$\Delta \text{Paup} = a + b \times \Delta \text{Out} + c \times \Delta \text{Old} + d \times \Delta \text{Pop} + \text{error}. \quad (1)$$

In this equation,

Δ is percentage change over time,

Paup is the number of Paupers

Out is the out-relief ratio N/D ,

N = number on welfare outside the poor-house,

D = number inside,

Old is the population over 65,

Pop is the population.

Data are from the English Censuses of 1871, 1881, and 1891. There are two Δ 's, one each for 1871–1881 and 1881–1891.

Relief policy was determined separately in each ‘union’, a small geographical area like a parish. At the time, there were about 600 unions, and Yule divides them into four kinds: rural, mixed, urban, metropolitan. There are $4 \times 2 = 8$ equations, one for each type of union and time period. Yule fits each equation to data by least squares. That is, he determines a , b , c , and d by minimizing the sum of squared errors,

$$\sum (\Delta \text{Paup} - a - b \times \Delta \text{Out} - c \times \Delta \text{Old} - d \times \Delta \text{Pop})^2.$$

The sum is taken over all unions of a given type in a given time period – which assumes, in essence, that coefficients are constant within each combination of geography and time. For example, consider the metropolitan unions. Fitting the equation to the data for 1871–1881, Yule gets

$$\Delta \text{Paup} = 13.19 + 0.755 \Delta \text{Out} - 0.022 \Delta \text{Old} - 0.322 \Delta \text{Pop} + \text{error}. \quad (2)$$

For 1881–1891, his equation is

$$\Delta \text{Paup} = 1.36 + 0.324 \Delta \text{Out} + 1.37 \Delta \text{Old} - 0.369 \Delta \text{Pop} + \text{error}. \quad (3)$$

The coefficient of ΔOut being relatively large and positive, Yule concludes that outrelief causes poverty.

Table 1 has the ratio of 1881 data to 1871 data for Pauperism, Out-relief ratio, Proportion of Old, and Population. If we subtract 100 from each entry, column 1 gives ΔPaup in equation (2). Columns 2, 3, 4 give the other variables. For Kensington (the first union in the table),

$$\Delta\text{Out} = 5 - 100 = -95, \Delta\text{Old} = 104 - 100 = 4,$$

$$\Delta\text{Pop} = 136 - 100 = 36.$$

The predicted value for ΔPaup from (2) is therefore

$$13.19 + 0.755 \times (-95) - 0.022 \times 4 \\ - 0.322 \times 36 = -70.$$

The actual value for ΔPaup is -73 , so the error is -3 . Other lines in the table are handled in a similar way. As noted above, coefficients were chosen to minimize the sum of the squared errors.

Quetelet [67] wanted to uncover 'social physics' – the laws of human behavior – by using statistical technique:

'In giving my work the title of Social Physics, I have had no other aim than to collect, in a uniform order, the phenomena affecting man, nearly as physical science brings together the phenomena appertaining to the material world. . . . in a given state of society, resting under the influence of certain causes, regular effects are produced, which oscillate, as it were, around a fixed mean point, without undergoing any sensible alterations.' . . .

'This study. . . has too many attractions – it is connected on too many sides with every branch of science, and all the most interesting questions in philosophy – to be long without zealous observers, who will endeavor to carry it further and further, and bring it more and more to the appearance of a science.'

Yule is using regression to infer the social physics of poverty. But this is not so easily to be done. Confounding is one issue. According to Pigou (a leading welfare economist of Yule's era), parishes with more efficient administrations were building poor-houses and reducing poverty. Efficiency of administration is then a confounder, influencing both the presumed cause and its effect. Economics may be another confounder. Yule occasionally tries to control for this, using the rate of population change as a proxy for economic growth. Generally, however, he pays little attention to economics. The explanation: 'A good deal of time and labour was spent in making trial of this idea, but the results proved unsatisfactory, and finally the measure was abandoned altogether. [p. 253]'

The form of Yule's equation is somewhat arbitrary, and the coefficients are not consistent over time and space. This is not necessarily fatal. However, unless the coefficients have some existence apart from the data, how can they predict the results of interventions that would change the data? The distinction between parameters and estimates runs throughout statistical theory; the discussion of response schedules, below, may sharpen the point.

There are other interpretive problems. At best, Yule has established association. Conditional on the covariates, there is a positive association between

ΔPaup and ΔOut . Is this association causal? If so, which way do the causal arrows point? For instance, a parish may choose not to build poor-houses in response to a short-term increase in the number of paupers. Then pauperism is the cause and outrelief the effect. Likewise, the number of paupers in one area may well be affected by relief policy in neighboring areas. Such issues are not resolved by the data analysis. Instead, answers are assumed *a priori*. Although he was busily parceling out changes in pauperism – so much is due to changes in out-relief ratios, so much to changes in other variables, so much to random effects – Yule was aware of the difficulties. With one deft footnote (number 25), he withdrew all causal claims: ‘Strictly speaking, for “due to” read “associated with”.’

Yule’s approach is strikingly modern, except there is no causal diagram with stars indicating statistical significance. Figure 1 brings him up to date. The arrow from ΔOut to ΔPaup indicates that ΔOut is included in the regression equation that explains ΔPaup . Three asterisks mark a high degree of statistical significance. The idea is that a statistically significant coefficient must differ from zero. Thus, ΔOut has a causal influence on ΔPaup . By contrast, a coefficient that lacks statistical significance is thought to be zero. If so, ΔOld would not exert a causal influence on ΔPaup .

The reasoning is seldom made explicit, and difficulties are frequently overlooked. Statistical assumptions are needed to determine significance from the data. Even if significance can be determined and the null hypothesis rejected or accepted, there is a deeper problem. To make causal inferences, it must be assumed that equations are stable under proposed interventions. Verifying such assumptions – without making the interventions – is problematic. On the other hand, if the coefficients and error terms change when variables are manipulated, the equation has

Figure 1 Yule’s model. Metropolitan unions, 1871–1881

only a limited utility for predicting the results of interventions.

Social Stratification

Blau and Duncan [12] are thinking about the stratification process in the United States. According to Marxists of the time, the United States is a highly stratified society. Status is determined by family background, and transmitted through the school system. Blau and Duncan present cross-tabs (in their Chapter 2) to show that the system is far from deterministic, although family background variables do influence status. The United States has a permeable social structure, with many opportunities to succeed or fail. Blau and Duncan go on to develop the path model shown in Figure 2, in order to answer questions like these:

‘how and to what degree do the circumstances of birth condition subsequent status? how does status attained (whether by ascription or achievement) at one stage of the life cycle affect the prospects for a subsequent stage?’

The five variables in the diagram are father’s education and occupation, son’s education, son’s first job, and son’s occupation. Data come from a special supplement to the March 1962 Current Population

Figure 2 Path model. Stratification, US, 1962

4 Linear Statistical Models for Causation

Survey. The respondents are the sons (age 20–64), who answer questions about current jobs, first jobs, and parents. There are 20 000 respondents. Education is measured on a scale from 0 to 8, where 0 means no schooling, 1 means 1–4 years of schooling, and so forth; 8 means some postgraduate education. Occupation is measured on Duncan’s prestige scale from 0 to 96. The scale takes into account income, education, and raters’ opinions of job prestige. Hucksters are at the bottom of the ladder, with clergy in the middle, and judges at the top.

How is Figure 2 to be read? The diagram unpacks to three regression equations:

$$U = aV + bX + \delta, \quad (4)$$

$$W = cU + dX + \epsilon, \quad (5)$$

$$Y = eU_i + fX + gW + \eta. \quad (6)$$

Parameters are estimated by least squares. Before regressions are run, variables are standardized to have mean 0 and variance 1. That is why no intercepts are needed, and why estimates can be computed from the correlations in Table 2.

In Figure 2, the arrow from V to U indicates a causal link, and V is entered on the right-hand side in the regression equation (4) that explains U . The path coefficient .310 next to the arrow is the estimated coefficient $\hat{a}$ of V . The number .859 on the ‘free arrow’ that points into U is the estimated standard deviation of the error term δ in (4). The other arrows are interpreted in a similar way. The curved line joining V and X indicates association rather than causation: V and X influence each other or are influenced by some common causes, not further analyzed in the diagram. The number on the curved line is just the correlation between V and X (Table 2). There are three equations because three variables in the diagram (U , W , Y) have arrows pointing into them.

The large standard deviations in Figure 2 show the permeability of the social structure. (Since variables are standardized, it is a little theorem that the standard deviations cannot exceed 1.) Even if father’s education and occupation are given, as well as respondent’s education and first job, the variation in status of current job is still large. As social physics, however, the diagram leaves something to be desired. Why linearity? Why are the coefficients the same for everybody? What about variables like intelligence or motivation? And where are the mothers?

The choice of variables and arrows is up to the analyst, as are the directions in which the arrows point. Of course, some choices may fit the data less well, and some may be illogical. If the graph is ‘complete’ – every pair of nodes joined by an arrow – the direction of the arrows is not constrained by the data [22 pp. 138, 142]. Ordering the variables in time may reduce the number of options.

If we are trying to find laws of nature that are stable under intervention, standardizing may be a bad idea, because estimated parameters would depend on irrelevant details of the study design (see below). Generally, the intervention idea gets muddier with standardization. Are means and standard deviations held constant even though individual values are manipulated? On the other hand, standardizing might be sensible if units are meaningful only in comparative terms (e.g., prestige points). Standardizing may also be helpful if the meaning of units changes over time (e.g., years of education), while correlations are stable. With descriptive statistics for one data set, it is really a matter of taste: do you like pounds, kilograms, or standard units? Moreover, all variables are on the same scale after standardization, which makes it easier to compare regression coefficients.

Table 2 Correlation matrix for variables in Blau and Duncan’s path model

		Y Sons’occ	W Sons’1 st job	U Sons’ed	X Dads’occ	V Dads’ed
Y	Sons’occ	1.000	.541	.596	.405	.322

U	Sons’ed	.596	.538	1.000	.438	.453
X	Dads’occ	.405	.417	.438	1.000	.516
V	Dads’ed	.322	.332	.453	.516	1.000

Hooke's Law

According to Hooke's law, stretch is proportional to weight. If weight x is hung on a spring, the length of the spring is $a + bx + \epsilon$, provided x is not too large. (Near the elastic limit of the spring, the physics will be more complicated.) In this equation, a and b are physical constants that depend on the spring not the weights. The parameter a is the length of the spring with no load. The parameter b is the length added to the spring by each additional unit of weight. The ϵ is random measurement error, with the usual assumptions. Experimental verification is a classroom staple.

If we were to standardize, the crucial slope parameter would depend on the weights and the accuracy of the measurements. Let v be the variance of the weights used in the experiment, let σ^2 be the variance of ϵ , and let s^2 be the mean square of the deviations from the fitted regression line. The standardized regression coefficient is

$$\sqrt{\frac{\hat{b}^2 v}{\hat{b}^2 v + s^2}} \approx \sqrt{\frac{b^2 v}{b^2 v + \sigma^2}}, \quad (7)$$

as can be verified by examining the sample covariance matrix. Therefore, the standardized coefficient depends on v and σ^2 , which are features of our measurement procedure not the spring.

Hooke's law is an example where regression is a very useful tool. But the parameter to estimate is b , the unstandardized regression coefficient. It is the unstandardized coefficient that says how the spring will respond when the load is manipulated. If a regression coefficient is stable under interventions, standardizing it is probably not a good idea, because stability gets lost in the shuffle. That is what (7) shows. Also see [4], ([11], p. 451).

Political Repression During the McCarthy Era

Gibson [28] tries to determine the causes of McCarthyism in the United States. Was repression due to the masses or the elites? He argues that elite intolerance is the root cause, the chief piece of evidence being a path model (Figure 3, redrawn from the paper). The dependent variable is a measure of repressive legislation in each state. The

independent variables are mean tolerance scores for each state, derived from the Stouffer survey of masses and elites. The 'masses' are just respondents in a probability sample of the population. 'Elites' include school board presidents, commanders of the American Legion, bar association presidents, labor union leaders. Data on masses were available for 36 states; on elites, for 26 states. The two straight arrows in Figure 3 represent causal links: mass and elite tolerance affect repression. The curved double-headed arrow in Figure 3 represents an association between mass and elite tolerance scores. Each one can influence the other, or both can have some common cause. The association is not analyzed in the diagram.

Gibson computes correlations from the available data, then estimates a standardized regression equation,

$$\begin{aligned} \text{Repression} = & \beta_1 \text{Mass tolerance} \\ & + \beta_2 \text{Elite tolerance} + \delta. \end{aligned} \quad (8)$$

He says, 'Generally, it seems that elites, not masses, were responsible for the repression of the era. . . . The beta for mass opinion is $-.06$; for elite opinion, it is $-.35$ (significant beyond .01)'.

The paper asks an interesting question, and the data analysis has some charm too. However, as social physics, the path model is not convincing. What hypothetical intervention is contemplated? If none, how are regressions going to uncover causal relationships? Why are relationships among the variables supposed to be linear? Signs apart, for example, why does a unit increase in tolerance have the same effect

Figure 3 Path model. The causes of McCarthyism

on repression as a unit decrease? Are there other variables in the system? Why are the states statistically independent? Such questions are not addressed in the paper.

McCarthy became a force in national politics around 1950. The turning point came in 1954, with public humiliation in the Army-McCarthy hearings. Censure by the Senate followed in 1957. Gibson scores repressive legislation over the period 1945–1965, long before McCarthy mattered, and long after. The Stouffer survey was done in 1954, when the McCarthy era was ending. The timetable is puzzling.

Even if such issues are set aside, and we grant the statistical model, the difference in path coefficients fails to achieve significance. Gibson finds that $\hat{\beta}_1$ is significant and $\hat{\beta}_2$ is insignificant, but that does not impose much of a constraint on $\hat{\beta}_1 - \hat{\beta}_2$. (The standard error for this difference can be computed from data generously provided in the paper.) Since $\beta_1 = \beta_2$ is a viable hypothesis, the data are not strong enough to distinguish masses from elites.

Inferring Causation by Regression

Path models are often thought to be rigorous statistical engines for inferring causation from association. Statistical techniques can be rigorous, given their assumptions. But the assumptions are usually imposed on the data by the analyst. This is not a rigorous process, and it is rarely made explicit. The assumptions have a causal component as well as a statistical component. It will be easier to proceed in terms of a specific example. In Figure 4, a hypothesized causal relationship between Y and Z is confounded by X . The free arrows leading into Y and Z are omitted.

The diagram describes two hypothetical experiments, and an observational study where the data are collected. The two experiments help to define the assumptions. Furthermore, the usual statistical analysis can be understood as an effort to determine what would happen under those assumptions *if* the experiments were done. Other interpretations of the analysis are not easily to be found. The experiments will now be described.

1. *First hypothetical experiment.* Treatment is applied to a subject, at level x . A response Y is observed,

Figure 4 Path model. The relationship between Y and Z is confounded by X . Free arrows leading into Y and Z are not shown

corresponding to the level of treatment. There are two parameters, a and b , that describe the response. With no treatment, the response level for each subject will be a , up to random error. All subjects are assumed to have the same value for a . Each additional unit of treatment adds b to the response. Again, b is the same for all subjects, at all levels of x , by assumption. Thus, if treatment is applied at level x , the response Y is assumed to be

$$a + bx + \text{random error.} \quad (9)$$

For Hooke's law, x is weight and Y is length of a spring under load x . For evaluation of job training programs, x might be hours spent in training and Y might be income during a follow-up period.

2. *Second hypothetical experiment.* In the second experiment, there are two treatments and a response variable Z . There are two treatments because there are two arrows leading into Z ; the treatments are labeled X and Y (Figure 4). Both treatments may be applied to a subject. There are three parameters, c , d , and e . With no treatment, the response level for each subject is taken to be c , up to random error. Each additional unit of treatment #1 adds d to the response. Likewise, each additional unit of treatment #2 adds e to the response. The constancy of parameters across subjects and levels of treatment is an assumption. If the treatments are applied at levels x and y , the response Z is assumed to be

$$c + dx + ey + \text{random error.} \quad (10)$$

Three parameters are needed because it takes three parameters to specify the linear relationship (10),

namely, an intercept and two slopes. Random errors in (9) and (10) are assumed to be independent from subject to subject, with a distribution that is constant across subjects; expectations are zero and variances are finite. The errors in (9) are assumed to be independent of the errors in (10).

The observational study. When using the path model in Figure 4 to analyze data from an observational study, we assume that levels for the variable X are independent of the random errors in the two hypothetical experiments (‘exogeneity’). In effect, we pretend that Nature randomized subjects to levels of X for us, which obviates the need for experimental manipulation. The exogeneity of X has a graphical representation: arrows come out of X , but no arrows lead into X .

We take the descriptions of the two experiments, including the assumptions about the response schedules and the random errors, as background information. In particular, we take it that Nature generates Y as if by substituting X into (9). Nature proceeds to generate Z as if by substituting X and Y – the same Y that has just been generated from X – into (10). In short, (9) and (10) are assumed to be the causal mechanisms that generate the observational data, namely, X , Y , and Z for each subject. The system is ‘recursive’, in the sense that output from (9) is used as input to (10) but there is no feedback from (9) to (8).

Under these assumptions, the parameters a , b can be estimated by regression of Y on X . Likewise, c , d , e can be estimated by regression of Z on X and Y . Moreover, these regression estimates have legitimate causal interpretations. This is because causation is built into the background assumptions, via the response schedules (9) and (10). If causation were not assumed, causation would not be demonstrated by running the regressions.

One point of running the regressions is usually to separate out direct and indirect effects of X on Z . The direct effect is d in (10). If X is increased by one unit with Y held fast, then Z is expected to go up by d units. But this is shorthand for the assumed mechanism in the second experiment. Without the thought experiments described by (9) and (10), how can Y be held constant when X is manipulated? At a more basic level, how would manipulation get into the picture?

Another path-analytic objective is to determine the effect e of Y on Z . If Y is increased by one unit with

X held fast, then Z is expected to go up by e units. (If $e = 0$, then manipulating Y would not affect Z , and Y does not cause Z after all.) Again, the interpretation depends on the thought experiments. Otherwise, how could Y be manipulated and X held fast?

To state the model more carefully, we would index the subjects by a subscript i in the range from 1 to n , the number of subjects. In this notation, X_i is the value of X for subject i . Similarly, Y_i and Z_i are the values of Y and Z for subject i . The level of treatment #1 is denoted by x , and $Y_{i,x}$ is the response for variable Y if treatment at level x is applied to subject i . Similarly, $Z_{i,x,y}$ is the response for variable Z if treatment #1 at level x and treatment #2 at level y are applied to subject i . The response schedules are to be interpreted causally:

- $Y_{i,x}$ is what Y_i would be if X_i were set to x by intervention.
- $Z_{i,x,y}$ is what Z_i would be if X_i were set to x and Y_i were set to y by intervention.

Counterfactual statements are even licensed about the past: $Y_{i,x}$ is what Y_i would have been, if X_i had been set to x . Similar comments apply to $Z_{i,x,y}$.

The diagram unpacks into two equations, which are more precise versions of (9) and (10), with a subscript i for subjects. Greek letters are used for the random error terms.

$$Y_{i,x} = a + bx + \delta_i. \quad (11)$$

$$Z_{i,x,y} = c + dx + ey + \epsilon_i. \quad (12)$$

The parameters a , b , c , d , e and the error terms δ_i , ϵ_i are not observed. The parameters are assumed to be the same for all subjects.

Additional assumptions, which define the statistical component of the model, are imposed on the error terms:

1. δ_i and ϵ_i are independent of each other within each subject i .
2. δ_i and ϵ_i are independent across subjects.
3. The distribution of δ_i is constant across subjects; so is the distribution of ϵ_i . (However, δ_i and ϵ_i need not have the same distribution.)
4. δ_i and ϵ_i have expectation zero and finite variance.
5. The δ ’s and ϵ ’s are independent of the X ’s.

The last is ‘exogeneity’.

8 Linear Statistical Models for Causation

According to the model, Nature determines the response Y_i for subject i by substituting X_i into (10):

$$Y_i = Y_{i,X_i} = a + bX_i + \delta_i. \quad (13)$$

Here, X_i is the value of X for subject i , chosen for us by Nature, as if by randomization. The rest of the response schedule – the $Y_{i,x}$ for other x – is not observed, and therefore stays in the realm of counterfactual hypotheticals. After all, even in an experiment, subject i would be assigned to one level of treatment, foreclosing the possibility of observing the response at other levels.

Similarly, we observe $Z_{i,x,y}$ only for $x = X_i$ and $y = Y_i$. The response for subject i is determined by Nature, as if by substituting X_i and Y_i into (12):

$$Z_i = Z_{i,X_i,Y_i} = c + dX_i + eY_i + \epsilon_i. \quad (14)$$

The rest of the response schedule, $Z_{i,x,y}$ for other x and y , remains unobserved. Economists call the unobserved $Y_{i,x}$ and $Z_{i,x,y}$ ‘potential outcomes’. The model specifies unobservable response schedules, not just regression equations. Notice too that a subject’s responses are determined by levels of treatment for that subject only. Treatments applied to subject j are not relevant to subject i . The response schedules (11) and (12) represent the causal assumptions behind the path diagram.

The conditional expectation of Y given $X = x$ is the average of Y for subjects with $X = x$. The formalism connects two very different ideas of conditional expectation: (a) finding subjects with $X = x$, versus (b) an intervention that sets X to x . The first is something you can actually do with observational data. The second would require manipulation. The model is a compact way of stating the assumptions that are needed to go from observational data to causal inferences.

In econometrics and cognate fields, ‘structural’ equations describe causal relationships. The model gives a clearer meaning to this idea, and to the idea of ‘stability under intervention’. The parameters in Figure 4, for instance, are defined through the response schedules (9) and (10), separately from the data. These parameters are constant across subjects and levels of treatment (by assumption, of course). Parameters are the same in a regime of passive observation and in a regime of active manipulation. Similar assumptions of stability are imposed on the error distributions. In summary, regression equations are

structural, with parameters that are stable under intervention, when the equations derive from response schedules like (11) and (12).

Path models do not infer causation from association. Instead, path models *assume* causation through response schedules, and – using additional statistical assumptions – estimate causal effects from observational data. The statistical assumptions (independence, expectation zero, constant variance) justify estimation by ordinary least squares. With large samples, confidence intervals and significance tests would follow. With small samples, the errors would have to follow a normal distribution in order to justify t Tests.

The box model in Figure 5 illustrates the statistical assumptions. Independent errors with constant distributions are represented as draws made at random with replacement from a box of potential errors [26]. Since the box remains the same from one draw to another, the probability distribution of one draw is the same as the distribution of any other. The distribution is constant. Furthermore, the outcome of one draw cannot affect the distribution of another. That is independence. Verifying the causal assumptions (11) and (12), which are about potential outcomes, is a daunting task. The statistical assumptions present difficulties of their own. Assessing the degree to which the modeling assumptions hold is therefore problematic. The difficulties noted earlier – in Yule on poverty, Blau and Duncan on stratification, Gibson on McCarthyism – are systemic.

Embedded in the formalism is the conditional distribution of Y , if we were to intervene and set the value of X . This conditional distribution is a counterfactual, at least when the study is observational. The conditional distribution answers the question, what would have happened if we had intervened and set X to x , rather than letting Nature take its course?

Figure 5 The path diagram as a box model

The idea is best suited to experiments or hypothetical experiments.

There are also nonmanipulationist ideas of causation: the moon causes the tides, earthquakes cause property values to go down, time heals all wounds. Time is not manipulable; neither are earthquakes or the moon. Investigators may hope that regression equations are like laws of motion in classical physics. (If position and momentum are given, you can determine the future of the system and discover what would happen with different initial conditions.) Some other formalism may be needed to make this nonmanipulationist account more precise.

Latent Variables

There is yet another layer of complexity when the variables in the path model remain ‘latent’ – unobserved. It is usually supposed that the manifest variables are related to the latent variables by a series of regression-like equations (‘measurement models’). There are numerous assumptions about error terms, especially when likelihood techniques are used. In effect, latent variables are reconstructed by some version of factor analysis and the path model is fitted to the results. The scale of the latent variables is not usually identifiable, so variables are standardized to have mean 0 and variance 1. Some algorithms will infer the path diagram as well as the latents from the data, but there are additional assumptions that come into play. Anderson [7] provides a rigorous discussion of statistical inference for models with latent variables, given the requisite statistical assumptions. He does not address the connection between the models and the phenomena. Kline [46] is a well-known text. Ullman and Bentler [78] survey recent developments.

A possible conflict in terminology should be mentioned. In psychometrics and cognate fields, ‘structural equation modeling’ (typically, path modeling with latent variables) is sometimes used for causal inference and sometimes to get parsimonious descriptions of covariance matrices. For causal inference, questions of stability are central. If no causal inferences are made, stability under intervention is hardly relevant; nor are underlying equations ‘structural’ in the econometric sense described earlier. The statistical assumptions (independence, distributions of error terms constant across subjects, parametric models for error distributions) would remain on the table.

Literature Review

There is by now an extended critical literature on statistical models, starting perhaps with the exchange between Keynes [44, 45] and Tinbergen [77]. Other familiar citations in the economics literature include Liu [52], Lucas [53], and Sims [71]. Manski [54] returns to the under-identification problem that was posed so sharply by Liu and Sims. In brief, *a priori* exclusion of variables from causal equations can seldom be justified, so there will typically be more parameters than data. Manski suggests methods for bounding quantities that cannot be estimated. Sims’ idea was to use simple, low-dimensional models for policy analysis, instead of complex-high dimensional ones. Leamer [48] discusses the issues created by specification searches, as does Hendry [35]. Heckman [33] traces the development of econometric thought from Haavelmo and Frisch onwards, stressing the role of ‘structural’ or ‘invariant’ parameters, and ‘potential outcomes’. Lucas too was concerned about parameters that changed under intervention. Engle, Hendry, and Richard [17] distinguish several kinds of exogeneity, with different implications for causal inference. Recently, some econometricians have turned to natural experiments for the evaluation of causal theories. These investigators stress the value of careful data collection and data analysis. Angrist and Krueger [8] have a useful survey.

One of the drivers for modeling in economics and other fields is rational choice theory. Therefore, any discussion of empirical foundations must take into account a remarkable series of papers, initiated by Kahneman and Tversky [41], that explores the limits of rational choice theory. These papers are collected in Kahneman, Slovic, and Tversky [40], and in Kahneman and Tversky [43]. The heuristics and biases program has attracted its own critics [29]. That critique is interesting and has some merit. But in the end, the experimental evidence demonstrates severe limits to the power of rational choice theory [42]. If people are trying to maximize expected utility, they generally do not do it very well. Errors are large and repetitive, go in predictable directions, and fall into recognizable categories. Rather than making decisions by optimization – or bounded rationality, or satisficing – people seem to use plausible heuristics that can be identified. If so, rational choice theory is generally not a good basis for justifying empirical models of behavior. Drawing in part on the work

of Kahneman and Tversky, Sen [69] gives a far-reaching critique of rational choice theory. This theory has its place, but also leads to ‘serious descriptive and predictive problems’.

Almost from the beginning, there were critiques of modeling in other social sciences too [64]. Bernert [10] reviews the historical development of causal ideas in sociology. Recently, modeling issues have been much canvassed in sociology. Abbott [2] finds that variables like income and education are too abstract to have much explanatory power, with a broader examination of causal modeling in Abbott [3]. He finds that ‘an unthinking causalism today pervades our journals’; he recommends more emphasis on descriptive work and on middle-range theories. Berk [9] is skeptical about the possibility of inferring causation by modeling, absent a strong theoretical base. Clogg and Haritou [14] review difficulties with regression, noting that you can too easily include endogenous variables as regressors.

Goldthorpe [30, 31, 32] describes several ideas of causation and corresponding methods of statistical proof, with different strengths and weaknesses. Although skeptical of regression, he finds rational choice theory to be promising. He favors use of descriptive statistics to determine social regularities, and statistical models that reflect generative processes. In his view, the manipulationist account of causation is generally inadequate for the social sciences. Hedström and Swedberg [34] present a lively collection of essays by sociologists who are quite skeptical about regression models; rational choice theory also takes its share of criticism. There is an influential book by Lieberman [50], with a follow-up by Lieberman and Lynn [51]. Ní Bhrolcháin [60] has some particularly forceful examples to illustrate the limits of modeling. Sobel [72] reviews the literature on social stratification, concluding that ‘the usual modeling strategies are in need of serious change’. Also see Sobel [73].

Meehl [57] reports the views of an empirical psychologist. Also see Meehl [56], with data showing the advantage of using regression to make predictions, rather than experts. Meehl and Waller [58] discuss the choice between two similar path models, viewed as reasonable approximations to some underlying causal structure, but do not reach the critical question – how to assess the adequacy of the approximation. Steiger [75] has a critical review of structural equation models. Larzalere and Kuhn [47] offer a more

general discussion of difficulties with causal inference by purely statistical methods. Abelson [1] has an interesting viewpoint on the use of statistics in psychology.

There is a well-known book on the logic of causal inference, by Cook and Campbell [15]. Also see Shadish, Cook, and Campbell [70], which has among other things a useful discussion of manipulationist versus nonmanipulationist ideas of causation. In political science, Duncan [16] is far more skeptical about modeling than Blau and Duncan [12]. Achen [5, 6] provides a spirited and reasoned defense of the models. Brady and Collier [13] compare regression methods with case studies; invariance is discussed under the rubric of causal homogeneity.

Recently, strong claims have been made for non-linear methods that elicit the model from the data and control for unobserved confounders [63, 74]. However, the track record is not encouraging [22, 24, 25, 39]. Cites from other perspectives include [55, 61, 62], as well as [18, 19, 20, 21, 23].

The statistical model for causation was proposed by Neyman [59]. It has been rediscovered many times since: see, for instance, [36, Section 9.4]. The setup is often called ‘Rubin’s model’, but that simply mistakes the history. See the comments by Dabrowska and Speed on their translation of Neyman [59], with a response by Rubin; compare to Rubin [68] and Holland [37]. Holland [37, 38] explains the setup with a super-population model to account for the randomness, rather than individualized error terms. Error terms are often described as the overall effects of factors omitted from the equation. But this description introduces difficulties of its own, as shown by Pratt and Schlaifer [65, 66]. Stone [76] presents a super-population model with some observed covariates and some unobserved. Formal extensions to observational studies – in effect, assuming these studies are experiments after suitable controls have been introduced – are discussed by Holland and Rubin among others.

Conclusion

Causal inferences can be drawn from nonexperimental data. However, no mechanical rules can be laid down for the activity. Since Hume, that is almost a truism. Instead, causal inference seems to require an enormous investment of skill, intelligence, and hard work. Many convergent lines of evidence must be

developed. Natural variation needs to be identified and exploited. Data must be collected. Confounders need to be considered. Alternative explanations have to be exhaustively tested. Before anything else, the right question needs to be framed. Naturally, there is a desire to substitute intellectual capital for labor. That is why investigators try to base causal inference on statistical models. The technology is relatively easy to use, and promises to open a wide variety of questions to the research effort. However, the appearance of methodological rigor can be deceptive. The models themselves demand critical scrutiny. Mathematical equations are used to adjust for confounding and other sources of bias. These equations may appear formidably precise, but they typically derive from many somewhat arbitrary choices. Which variables to enter in the regression? What functional form to use? What assumptions to make about parameters and error terms? These choices are seldom dictated either by data or prior scientific knowledge. That is why judgment is so critical, the opportunity for error so large, and the number of successful applications so limited.

Acknowledgments

Richard Berk, Persi Diaconis, Michael Finkelstein, Paul Humphreys, Roger Purves, and Philip Stark made useful comments. This paper draws on Freedman [19, 20, 22–24]. Figure 1 appeared in Freedman [21, 24]; figure 2 is redrawn from Blau and Duncan [12]; figure 3, from Gibson [28], also see Freedman [20].

Linkage Analysis

Genetic linkage refers to the nonindependent segregation of the alleles at genetic loci close to one another on the same chromosome. Mendel's law of segregation states that an individual with heterozygous genotype (Aa) has equal probability of transmitting either allele (A or a) to an offspring. The same is true of any other locus with alleles B and b. Under Mendel's second law, that of independent assortment, the probabilities of transmitting the four possible combinations of alleles (AB, Ab, aB, ab) are all equal, namely *one-quarter*. This law is, however, only true for pairs of loci that are on separate chromosomes. For two loci that are on the same chromosome (known technically as syntenic), the probabilities of the four gametic classes (AB, Ab, aB, ab) are not equal, with an excess of the same allelic combinations as those that were transmitted to the individual from his or her parents. In other words, if the individual received the allelic combination AB from one parent and ab from the other, then he or she will transmit these same combinations with greater probabilities than the others (i.e., Ab and aB). The former allelic combinations are known as parental types and the latter, recombinants. The strength of genetic linkage between two loci is measured by the recombination fraction, defined as the probability that a recombinant of the two loci is transmitted to an offspring. Recombination fraction ranges from 0 (complete linkage) to 0.5 (complete absence of linkage).

Recombinant gametes of two syntenic loci are generated by the crossing-over of homologous chromosomes at certain semirandom locations during meiosis. The smaller the distance between two syntenic loci, the less likely that they will be separated by crossing-over, and therefore the smaller the recombination fraction. A recombination of 0.01 corresponds approximately to a genetic map distance of 1 centiMorgan (cM). The crossing-over rate varies between males and females, and for different chromosomal regions, but on average a genetic distance of 1 cM corresponds approximately to a physical distance of one million DNA base pairs. The total genetic length of the human genome is approximately 3500 cM.

Mapping Disease Genes by Linkage Analysis

For many decades, linkage analysis was restricted to Mendelian phenotypes such as the ABO blood groups and HLA antigens. Recent developments in molecular genetics have enabled nonfunctional polymorphisms to be detected and measured. Standard sets of such genetic markers, evenly spaced throughout the entire genome, have been developed for systematic linkage analysis to localize genetic variants that increase the risk of disease. This is a particularly attractive method of mapping the genes for diseases since no knowledge of the pathophysiology is required. For this reason, the use of linkage analysis to map disease genes is also called *positional cloning*.

Linkage Analysis for Mendelian Diseases

Linkage analysis in humans presents interesting statistical challenges. For Mendelian diseases, the challenges are those of variable pedigree structure and size, and the common occurrence of missing data. The standard method of analysis involves calculating the likelihood with respect to the recombination fraction between disease and marker loci, or the map position of the disease locus in relation to a set of marker loci, while the disease model is assumed known (e.g., dominant or recessive). Traditionally, the strength of evidence for linkage is summarized as a lod score, defined as the common (i.e., base10) logarithm of the ratio of the likelihood given a certain recombination fraction between marker and disease loci to that under no linkage. The likelihood calculations were traditionally accomplished by use of the Elston–Stewart Algorithm, implemented in linkage analysis programs such as LINKAGE and VITESSE. A lod score of 3 or more is conventionally regarded as significant evidence of linkage. For Mendelian disorders, 98% of reports of linkage that meet this criterion have been subsequently confirmed. Linkage analysis has successfully localized and identified the genes for hundreds of Mendelian disorders.

In multipoint linkage analysis, the likelihood (*see Maximum Likelihood Estimation*) is evaluated for different chromosomal locations of the disease locus relative to a fixed set of genetic markers, and lod scores are defined as the common (i.e., base10)

2 Linkage Analysis

logarithm of the ratio of the likelihood given certain positions of the disease locus on the map to that at an unlinked location. Multipoint calculations present serious computational difficulties for the Elston–Stewart Algorithm, but for modest size, pedigrees are feasible using the Lander–Green, implemented for example in GENEHUNTER, ALLEGRO, and MERLIN.

In both two-point and multipoint lod score analyses, it is standard to assume a generalized single locus model, in which the parameters, namely, the frequencies of the disease and normal alleles (A and a), and the probabilities of disease given the three genotypes (AA , Aa , and aa) are specified by the user. For example, for a rare dominant condition, the allele frequency of the disease allele (A) is set to be a low value, while the probabilities of disease given the AA , Aa , aa genotypes are set at close to 1, 1, and 0, respectively. Similarly, for a recessive condition the allele frequency of the disease allele (A) is set to be a moderate value, the probabilities of disease given the AA , Aa , aa genotypes are set at close to 1, 0, and 0, respectively. The need to assume a generalized single locus model and to specify the parameters of such a model has led to the terms model-based or parametric linkage analysis.

Locus heterogeneity in linkage analysis refers to the situation in which the mode of inheritance, but not the actual disease locus, is the same across different pedigrees. In other words, there are multiple disease loci that are indistinguishable from each other both in terms of manifestations at the individual level and in the pattern of familial transmission. Under these circumstances, the power to detect linkage is much diminished, even with lod scores modified to take account of locus heterogeneity (hlod), especially for samples consisting of small pedigrees. Because of this, linkage analysis has the greatest chance of success when carried out on large pedigrees with multiple affected members.

Linkage Analysis for Complex Traits

For common diseases that do not show a simple Mendelian pattern of inheritance and are therefore likely to be the result of multiple genetic and environmental factors, linkage analysis is a difficult task. For such diseases, we typically would have an idea

of the overall importance of genetic factors (i.e., **heritability**) but no detailed knowledge of genetic architecture in terms of the number of vulnerability genes or the magnitude of their effects. There are two major approaches to the linkage analysis of such complex diseases. The first is to adopt a lod score approach, but modified to allow for a number of more or less realistic models for the genotype–phenotype relationship, and to adjust the largest lod score over these models for multiple testing. The second approach is ‘model-free’ in the sense that a disease model does not have to be specified for the analysis. Instead, the analysis proceeds by defining some measure of allele sharing between individuals in a pedigree, and relating the extent of allele sharing to phenotypic similarity.

One popular version of model-free linkage analysis is the affected sib-pair (ASP) method, which is based on the detection of excessive allele sharing at a marker locus for a sample of sibling pairs where both members are affected by the disorder. The usual definition of allele sharing in model-free linkage analysis is ‘identity-by-descent’, which refers to alleles that are descended from (and are therefore replicates of) a single ancestral allele in a recent common ancestor. Algorithms for estimating the extent of local IBD from marker genotype data have been developed and implemented in programs such as ERPA, GENEHUNTER, and MERLIN. Generalizations of the ASP method to other family structures with multiple affected individuals have resulted in nonparametric linkage (NPL) statistics and their improved likelihood-based versions developed by Kong and Cox.

Methods of linkage analysis have been developed also for quantitative traits (e.g., blood pressure, body mass index). A particularly simple method is based on a regression of phenotypic similarity on allele sharing, developed by Haseman and Elston. A more sophisticated approach is based on a variance components model, in which a component of variance is specified to have covariance between relatives that is proportional to the extent of allele sharing between the relatives. However, the Haseman–Elston approach has been modified so that it can be applied to general pedigrees selected to contain individuals with extreme trait values.

Regardless of the statistical method used for the linkage analysis of complex traits, there are two major inherent limitations of the approach. The

first is that the sample sizes required to detect a locus with a small effect size are very large, potentially many thousands of families. The second is low resolving power, in that the region that shows linkage is typically very broad, covering a region with potentially hundreds of genes. For these

reasons, linkage is usually combined with association strategy in the search for the genetic determinants of multigenic diseases.

Logistic Regression

Logistic regression is a method for predicting the outcomes of ‘either-or’ trials. Either-or trials occur frequently in research. A person responds appropriately to a drug or does not; the dose of the drug may affect the outcome. A person may support a political party or not; the response may be related to their income. A person may have a heart attack in a 10-year period; the response may be related to age, weight, blood pressure, or cholesterol. We discuss basic ideas of modeling in the section titled ‘Basic Ideas’ and basic ideas of data analysis in the section titled ‘Fundamental Data Analysis’. Subsequent sections examine model testing, variable selection, outliers and influential observations, methods for testing lack of fit, exact conditional inference, random effects, and Bayesian analysis.

Basic Ideas

A binary response is one with two outcomes. Denote these as $y = 1$ indicating ‘success’ and $y = 0$ indicating ‘failure’. Let p denote the probability of getting the response $y = 1$, so

$$\Pr[y = 1] = p, \quad \Pr[y = 0] = 1 - p. \quad (1)$$

Let predictor variables such as age, weight, blood pressure, and cholesterol be denoted $x_1, x_2, \dots, x_{k-1}$. A logistic regression model is a method for relating the probabilities to the predictor variables. Specifically, logistic regression is a **linear model** for the logarithm of the odds of success. The odds of success are $p/(1 - p)$ and a linear model for the log odds is

$$\log \left[\frac{p}{1 - p} \right] = \beta_0 + \beta_1 x_1 + \dots + \beta_{k-1} x_{k-1}. \quad (2)$$

Here the β_j s are unknown regression coefficients. For simplicity of notation, let the log odds be

$$\eta = \beta_0 + \beta_1 x_1 + \dots + \beta_{k-1} x_{k-1}. \quad (3)$$

It follows that

$$p = \frac{e^\eta}{1 + e^\eta}, \quad 1 - p = \frac{1}{1 + e^\eta}. \quad (4)$$

The transformation that changes η into p is known as the ‘logistic’ transformation, hence the name logistic regression. The transformation $\log[p/(1 - p)] = \eta$ is known as the ‘logit’ transformation. Logit models are the same thing as logistic models. In fact, it is impossible to perform logistic regression without using both the logistic transformation and the logit transformation. Historically, ‘logistic regression’ described models for continuous predictor variables $x_1, x_2, \dots, x_{k-1}$ such as age and weight, while ‘logit models’ were used for categorical predictor variables such as sex, race, and alternative medical treatments. Such distinctions are rarely made anymore.

Typical data consist of independent observations on, say, n individuals. The data are a collection $(y_i, x_{i1}, \dots, x_{i,k-1})$ for $i = 1, \dots, n$ with y_i being 1 or 0 for the i th individual and x_{ij} being the value of the j th predictor variable on the i th individual. For example, Christensen [3] uses an example from the Los Angeles Heart Study (LAHS) that involves $n = 200$ men: y_i is 1 if an individual had a coronary incident in the previous 10 years; $k - 1 = 6$ with x_{i1} = age, x_{i2} = systolic blood pressure, x_{i3} = diastolic blood pressure, x_{i4} = cholesterol, x_{i5} = height, and x_{i6} = weight for a particular individual. The specific logistic regression model is

$$\log \left[\frac{p_i}{1 - p_i} \right] = \beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2} + \beta_3 x_{i3} + \beta_4 x_{i4} + \beta_5 x_{i5} + \beta_6 x_{i6}. \quad (5)$$

Note that the model involves $k = 7$ unknown β_j parameters.

There are two ways of analyzing logistic regression models: frequentist methods and Bayesian methods. Historically, logistic regression was developed after standard regression (see **Multiple Linear Regression**) and has been taught to people who already know standard regression. The methods of analysis are similar to those for standard regression.

Fundamental Data Analysis

Standard methods for frequentist analysis depend on the assumption that the sample size n is large relative to the number of β_j parameters in the model, that is, k . The usual results of the analysis are estimates of the β_j s, say $\hat{\beta}_j$ s, and standard errors for the $\hat{\beta}_j$ s, say

2 Logistic Regression

$SE(\hat{\beta}_j)$ s. In addition, a likelihood ratio test statistic, also known as a *deviance* (D), and *degrees of freedom* (df) for the deviance are given. The degrees of freedom for the deviance are $n - k$. (Some computer programs give alternative versions of the deviance that are less useful. This will be discussed later but can be identified by the fact that the degrees of freedom are less than $n - k$.)

The β_j s are estimated by choosing values that maximize the *likelihood function*,

$$L(\beta_0, \dots, \beta_{k-1}) = \prod_{i=1}^n p_i^{y_i} (1 - p_i)^{1-y_i}, \quad (6)$$

wherein it is understood that the p_i s depend on the β_j s through the logistic regression model. Such estimates are called **maximum likelihood estimates**. The deviance can be taken as

$$D = -2 \log[L(\hat{\beta}_0, \dots, \hat{\beta}_{k-1})]. \quad (7)$$

For example, in the LAHS data

Variable	$\hat{\beta}_j$	$SE(\hat{\beta}_j)$
Intercept	-4.5173	7.451
x_1	0.04590	0.02344
x_2	0.00686	0.02013
x_3	-0.00694	0.03821
x_4	0.00631	0.00362
x_5	-0.07400	0.1058
x_6	0.02014	0.00984
$D = 134.9,$		$df = 193$

Given this information, a number of results can be obtained. For example, β_6 is the regression coefficient for weight. A 95% **confidence interval** for β_6 has endpoints

$$\hat{\beta}_6 \pm 1.96 SE(\hat{\beta}_6) \quad (8)$$

and is (0.00085, 0.03943). The value 1.96 is the 97.5% point of a standard normal distribution. To test $H_0: \beta_6 = 0$, one looks at

$$\frac{\hat{\beta}_6 - 0}{SE(\hat{\beta}_6)} = \frac{0.02014 - 0}{0.00984} = 2.05 \quad (9)$$

The P value for this test is .040, which is the probability that a standard normal random variable

is greater than 2.05 or less than -2.05. To test $H_0: \beta_6 = 0.01$, one looks at

$$\frac{\hat{\beta}_6 - 0.01}{SE(\hat{\beta}_6)} = \frac{0.02014 - 0.01}{0.00984} = 1.03 \quad (10)$$

and obtains a P value by comparing 1.03 to a standard normal distribution. The use of the standard normal distribution is an approximation based on having n much larger than k .

Perhaps the most useful things to estimate in logistic regression are probabilities. The estimated log odds are

$$\log \left[\frac{\hat{p}}{1 - \hat{p}} \right] = \hat{\beta}_0 + \hat{\beta}_1 x_1 + \hat{\beta}_2 x_2 + \hat{\beta}_3 x_3 + \hat{\beta}_4 x_4 + \hat{\beta}_5 x_5 + \hat{\beta}_6 x_6. \quad (11)$$

For a 60-year-old man with blood pressure of 140 over 90, a cholesterol reading of 200, who is 69 inches tall and weighs 200 pounds, the estimated log odds of a coronary incident are

$$\begin{aligned} \log \left[\frac{\hat{p}}{1 - \hat{p}} \right] &= -4.5173 + .04590(60) \\ &+ .00686(140) - .00694(90) + .00631(200) \\ &- 0.07400(69) + 0.02014(200) = -1.2435. \end{aligned} \quad (12)$$

The probability of a coronary incident is estimated as

$$\hat{p} = \frac{e^{-1.2435}}{1 + e^{-1.2435}} = .224. \quad (13)$$

To see what the model says about the effect of age (x_1) and cholesterol (x_4), one might plot the estimated probability of a coronary incident as a function of age for people with blood pressures, height, and weight of $x_2 = 140$, $x_3 = 90$, $x_5 = 69$, $x_6 = 200$, and, say, both cholesterol $x_4 = 200$ and $x_4 = 300$. Unfortunately, while confidence intervals for this p can be computed without much difficulty, they are not readily available from many computer programs.

Testing Models

The deviance D and its degrees of freedom are useful for comparing alternative logistic regression models.

The actual number reported in the example, $D = 134.9$ with $193df$, is of little use by itself without

another model to compare it to. The value $D = 134.9$ is found by comparing the 7 variable model to a model with $n = 200$ parameters while we only have $n = 200$ observations. Clearly, 200 observations is not a large sample relative to a model with 200 parameters, hence large sample theory does not apply and we have no way to evaluate whether $D = 134.9$ is an appropriate number.

What we can do is compare the 6 predictor variable model (full model) with $k = 7$ to a smaller model (reduced model) involving, say, only age and weight,

$$\log \left[\frac{p_i}{1 - p_i} \right] = \beta_0 + \beta_1 x_{i1} + \beta_6 x_{i6} \quad (14)$$

which has $k = 3$. Fitting this model gives

Variable	$\hat{\beta}_j$	SE($\hat{\beta}_j$)
Intercept	-7.513	1.706
x_1	0.06358	0.01963
x_6	0.01600	0.00794
$D = 138.8,$		$df = 197.$

To test the adequacy of the reduced model compared to the full model compute the difference in the deviances, $D = 138.8 - 134.9 = 3.9$ and compare that to a chi-squared distribution with degrees of freedom determined by the difference in the deviance degrees of freedom, $197 - 193 = 4$. The probability that a $\chi^2(4)$ distribution is greater than 3.9 is .42, which is the P value for the test.

There is considerable flexibility in the model testing approach. Suppose we suspect that it is not the blood pressure readings that are important but rather the difference between the blood pressure readings, $(x_2 - x_3)$. We can construct a model that has $\beta_3 = -\beta_2$. If we incorporate this hypothesis into the full model, we get

$$\begin{aligned} \log \left[\frac{p_i}{1 - p_i} \right] &= \beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2} + (-\beta_2) x_{i3} + \beta_4 x_{i4} \\ &\quad + \beta_5 x_{i5} + \beta_6 x_{i6} \\ &= \beta_0 + \beta_1 x_{i1} + \beta_2 (x_{i2} - x_{i3}) + \beta_4 x_{i4} \\ &\quad + \beta_5 x_{i5} + \beta_6 x_{i6} \end{aligned} \quad (15)$$

which gives $D = 134.9$ on $df = 194$. This model is a special case of the full model, so a test of the

models has

$$D = 134.9 - 134.9 = 0, \quad (16)$$

with $df = 194 - 193 = 1$. The deviance difference is essentially 0, so the data are consistent with the reduced model.

This is a good time to discuss the alternate deviance computation. Logistic regression does not need to be performed on binary data. It can be performed on binomial data. Binomial data consist of the number of successes in a predetermined number of trials. The data would be $(N_i, y_i, x_{i1}, \dots, x_{i,k-1})$ for $i = 1, \dots, n$ where N_i is the number of trials in the i th case, y_i is the number of successes, and the predictor variables are as before. The logistic model is identical since it depends only on p_i , the probability of success in each trial, and the predictor variables. The likelihood and deviance require minor modifications.

For example, in our $k = 3$ model with age and weight, some computer programs will pool together all the people that have the same age and weight when computing the deviance. If there are 5 people with the same age-weight combination, they examine the number of coronary incidents out of this group of 5. Instead of having $n = 200$ cases, these 5 cases are treated as one case and n is reduced to $n - 4 = 196$. There can be several combinations of people with the same age and weight, thus reducing the effective number of cases even further. Call this new number of effective cases n' . The degrees of freedom for this deviance will be $n' - k$, which is different from the $n - k$ one gets using the original deviance computation. If the deviance degrees of freedom are something other than $n - k$, the computer program is using the alternative deviance computation.

Our original deviance compares the $k = 3$ model based on intercept, age, and weight to a model with $n = 200$ parameters and large sample theory does not apply. The alternative deviance compares the $k = 3$ model to a model with n' parameters, but in most cases, large sample theory will still not apply. (It should apply better. The whole point of the alternative computation is to make it apply better. But with binary data and continuous predictors, it rarely applies well enough to be useful.)

The problem with the alternative computation is that pooling cases together eliminates our ability to

use the deviance for model comparisons. In comparing our $k = 3$ model with our $k = 7$ model, it is likely that, with $n = 200$ men, some of them would have the same age and weight. However, it is very unlikely that these men would also have the same heights, blood pressures, and cholesterols. Thus, different people get pooled together in different models, and this is enough to invalidate model comparisons based on these deviances.

Variable Selection

Variable selection methods from standard regression such as forward selection, backwards elimination, and stepwise selection of variables carry over to logistic regression with almost no change. Extending the ideas of best subset selection from standard regression to logistic regression is more difficult.

One approach to best subset selection in logistic regression is to compare all possible models to the model

$$\log \left[\frac{p_i}{1 - p_i} \right] = \beta_0 \quad (17)$$

by means of score tests. The use of score tests makes this computationally feasible but trying to find a good model by comparing various models to a poor model is a bad idea. Typically, model (17) will fit the data poorly because it does not involve any of the predictor variables. A better idea is to compare the various candidate models to the model that contains all of the predictor variables. In our example, that involves comparing the $2^6 = 64$ possible models (every variable can be in or out of a possible model) to the full 6 variable ($k = 7$) model. Approximate methods for doing this are relatively easy (see [11] or [3, Section 4.4]), but are not commonly implemented in computer programs.

As in standard regression, if the predictor variables are highly correlated, it is reasonable to deal with the *collinearity* by performing *principal components regression* (see **Principal Component Analysis**). The principal components depend only on the predictor variables, not on y . In particular, the principal components do not depend on whether y is binary (as is the case here) or is a measurement (as in standard regression).

Outliers and Influential Observations

In standard regression, one examines potential **outliers** in the dependent variable y and unusual combinations of the predictor variables $(x_1, \dots, x_{k-1})$. Measures of influence combine information on the unusualness of y and $(x_1, \dots, x_{k-1})$ into a single number.

In binary logistic regression, there is really no such thing as an outlier in the y s. In binary logistic regression, y is either 0 or 1. Only values other than 0 or 1 could be considered outliers. Unusual values of y relate to what our model tells us about y . Young, fit men have heart attacks. They do not have many heart attacks, but some of them do have heart attacks. These are not outliers, they are to be expected. If we see a lot of young, fit men having heart attacks and our model does not explain it, we have a problem with the model (lack of fit), rather than outliers. Nonetheless, having a young fit man with a heart attack in our data would have a large influence on the overall nature of the fitted model. It is interesting to identify cases that have a large influence on different aspects of the fitted model.

Many of the influence measures from standard regression have analogues for logistic regression. Unusual combinations of predictor variables can be identified using a modification of the leverage. Analogues to Cook's distance (see **Multiple Linear Regression**) measure the influence (see **Influential Observations**) of an observation on estimated regression coefficients and on changes in the fitted log odds ($\hat{\eta}_i$ s). Pregibon [12] first developed diagnostic measures for logistic regression. Johnson [8] pointed out that influence measures should depend on the aspects of the model that are important in the application.

Testing Lack of Fit

Lack of fit occurs when the model being used is inadequate to explain the data. The basic problem in testing lack of fit is to dream up a model that is more general than the one currently being used but that has a reasonable chance of fitting the data. Testing the current (reduced) model against the more general (full) model provides a test for lack of fit. This is a modeling idea, so

the relevant issues are similar to those for standard regression.

One method of obtaining a more general model is to use a basis expansion. The idea of a basis expansion is that for some unknown continuous function of the predictor variables, say, $f(x_1, \dots, x_{k-1})$, the model $\log[p/(1-p)] = f(x_1, \dots, x_{k-1})$ should be appropriate. In turn, $f(x_1, \dots, x_{k-1})$ can be approximated by linear combinations of known functions belonging to some collection of basis functions. The basis functions are then used as additional predictor variables in the logistic regression so that this more general model can approximate a wide variety of possible models. The most common method for doing this is simply to fit additional polynomial terms. In our example, we could incorporate additional terms for age squared (x_1^2), age cubed (x_1^3), height squared times weight cubed ($x_5^2 x_6^3$), etc. Alternatives to fitting additional polynomial terms would be to add trigonometric terms such as $\sin(2x_1)$ or $\cos(3x_4)$ to the model. (Typically, the predictor variables should be appropriately standardized before applying trigonometric functions.) Other options are to fit wavelets or even splines (see **Scatterplot Smoothers**). See [4, Chapter 7] for an additional discussion of these methods.

A problem with this approach is that the more general models quickly become unwieldy. For example, with the LAHS data, an absolute minimum for a basis expansion would be to add all the terms x_{ik}^2 , $k = 1, \dots, 6$ and all pairs $x_{ik}x_{ik'}$ for $k \neq k'$. Including all of the original variables in the model, this gives us a new model with $1 + 6 + 6 + 15 = 28$ parameters for only 200 observations. A model that includes all possible second-order polynomial terms involves $3^6 = 729$ parameters.

An alternative to using basis expansions is to partition the predictor variable data into subsets. For example, if the subsets constitute sets of predictor variables that are nearly identical, one could fit the original model but add a separate intercept effect for each near replicate group. Alternatively, one could simply fit the entire model on different subsets and see whether the model changes from subset to subset. If it changes, it suggests lack of fit in the original model. Christensen [5, Section 6.6] discusses these ideas for standard regression.

A commonly used partitioning method involves creating subsets of the data that have similar $\hat{p}_i$ values. This imposes a partition on the predictor

variables. However, allowing the subsets to depend on the binary data (through the fitted values $\hat{p}_i$) causes problems in terms of finding an appropriate reference distribution for the difference in deviances test statistic. The usual χ^2 distribution does not apply for partitions selected using the binary data, see [7].

Landwehr, Pregibon, and Shoemaker [9] have discussed graphical methods for detecting lack of fit.

Exact Conditional Analysis

An alternative to the methods of analysis discussed above are methods based on exact conditional tests and their related confidence regions. These methods are mathematically correct, have the advantage of not depending on large sample approximations for their validity, and are similar in spirit to *Fisher's exact test* (see **Exact Methods for Categorical Data**) for **2 x 2 contingency tables**. Unfortunately, they are computationally intensive and require specialized software. From a technical perspective, they involve treating certain random quantities as fixed in order to perform the computations. Whether it is appropriate to fix (i.e., condition on) these quantities is an unresolved philosophical issue. See [1, Section 5] or, more recently, [10] for a discussion of this approach.

Random Effects

Mixed models are models in which some of the β_j coefficients are unobservable random variables rather than being unknown fixed coefficients. These random effects are useful in a variety of contexts. Suppose we are examining whether people are getting adequate pain relief. Further suppose we have some predictor variables such as age, sex, and income, say, x_1, x_2, x_3 . The responses y are now 1 if pain relief is adequate and 0 if not, however, the data involve looking at individuals on multiple occasions. Suppose we have n individuals and each individual is evaluated for pain relief T times. The overall data are y_{ij} , $i = 1, \dots, n$; $j = 1, \dots, T$. The responses on one individual should be more closely related than responses on different individuals and that can be incorporated into the model by using a random effect. For example, we might have a model in which, given an effect for individual i , say, β_{i0} , the y_{ij} s are

independent with probability determined by

$$\log \left[\frac{p_{ij}}{1 - p_{ij}} \right] = \beta_{i0} + \beta_1 x_{ij1} + \beta_2 x_{ij2} + \beta_3 x_{ij3}. \quad (18)$$

However, $\beta_{10}, \dots, \beta_{n0}$ are independent observations from a $N(\beta_0, \sigma^2)$ distribution. With this model, observations on different people are independent but observations on a given person i are dependent because they all depend on the outcome of the common random variable β_{i0} . Notice that the variables x_{ijs} are allowed to vary over the T times, even though in our description of the problem variables like age, sex, and income are unlikely to change substantially over the course of a study.

Such random effects models are examples of **generalized linear mixed models**. These are much more difficult to analyze than standard logistic regression models unless you perform a Bayesian analysis, see the section titled ‘Bayesian Analysis’.

Bayesian Analysis

Bayesian analysis (see **Bayesian Statistics**) involves using the data to update the analyst’s beliefs about the problem. It requires the analyst to provide a probability distribution that describes his knowledge/uncertainty about the problem prior to data collection. It then uses the likelihood function to update those views into a ‘posterior’ probability distribution.

Perhaps the biggest criticism of the Bayesian approach is that it is difficult and perhaps even inappropriate for the analyst to provide a prior probability distribution. It is difficult because it typically involves giving a prior distribution for the k regression parameters. The regression parameters are rather esoteric quantities and it is difficult to quantify knowledge about them. Tsutakawa and Lin [13] and Bedrick, Christensen, and Johnson [2] argued that it is more reasonable to specify prior distributions for the probabilities of success at various combinations of the predictor variables and to use these to induce a prior probability distribution on the regression coefficients. The idea that it may be inappropriate to specify a prior distribution is based on the fact that different analysts will have different information and thus can arrive at different results. Many practitioners of Bayesian analysis would argue that with sufficient

data, different analysts will substantially agree in their results and with insufficient data it is appropriate that they should disagree.

One advantage of Bayesian analysis is that it does not rely on large sample approximations. It is based on exact distributional results, although in practice it relies on computers to approximate the exact distributions. It requires specialized software, but such software is freely available. Moreover, the Bayesian approach deals with more complicated models, such as random effects models (see **Random Effects in Multivariate Linear Models: Prediction**), with no theoretical and minimal computational difficulty. See [6] for a discussion of Bayesian methods.

Log-linear Models

Introduction

Log-linear analysis has become a widely used method for the analysis of multivariate frequency tables obtained by cross-classifying sets of nominal, ordinal, or discrete interval level variables. (see **Scales of Measurement**) Examples of textbooks discussing categorical data analysis by means of log-linear models are [2], [4], [14], [15], [16], and [27].

We start by introducing the standard hierarchical log-linear modelling framework. Then, attention is paid to more advanced types of log-linear models that make it possible to impose interesting restrictions on the model parameters, for example, restrictions for ordinal variables. Subsequently, we present ‘regression analytic’, ‘path-analytic’, and ‘factor-analytic’ variants of log-linear analysis. The last section discusses parameter estimation by **maximum likelihood**, testing, and software for log-linear analysis.

Hierarchical Log-linear Models

Saturated Models

Suppose we have a frequency table formed by three categorical variables which are denoted by A , B , and C , with indices a , b , and c . The number of categories of A , B , and C is denoted by A^* , B^* , and C^* , respectively. Let m_{abc} be the expected frequency for the cell belonging to category a of A , b of B , and c of C . The saturated log-linear model for the three-way table ABC is given by

$$\log m_{abc} = \lambda + \lambda_a^A + \lambda_b^B + \lambda_c^C + \lambda_{ab}^{AB} + \lambda_{ac}^{AC} + \lambda_{bc}^{BC} + \lambda_{abc}^{ABC}. \quad (1)$$

It should be noted that the log transformation of m_{abc} is tractable because it restricts the expected frequencies to remain within the admissible range. The consequence of specifying a linear model for the log of m_{abc} is that a multiplicative model is obtained for m_{abc} , that is,

$$m_{abc} = \exp(\lambda + \lambda_a^A + \lambda_b^B + \lambda_c^C + \lambda_{ab}^{AB} + \lambda_{ac}^{AC} + \lambda_{bc}^{BC} + \lambda_{abc}^{ABC})$$

$$= \tau \tau_a^A \tau_b^B \tau_c^C \tau_{ab}^{AB} \tau_{ac}^{AC} \tau_{bc}^{BC} \tau_{abc}^{ABC}. \quad (2)$$

From (1) and (2), it can be seen that the saturated model contains all interactions terms among A , B , and C . That is, no *a priori* restrictions are imposed on the data. However, (1) and (2) contain too many parameters to be identifiable. Given the values for the expected frequencies m_{abc} , there is not a unique solution for the λ and τ parameters. Therefore, constraints must be imposed on the log-linear parameters to make them identifiable. One option is to use **analysis of variance** (ANOVA)-like constraints, namely,

$$\begin{aligned} \sum_a \lambda_a^A &= \sum_b \lambda_b^B = \sum_c \lambda_c^C = 0, \\ \sum_a \lambda_{ab}^{AB} &= \sum_b \lambda_{ab}^{AB} = \sum_a \lambda_{ac}^{AC} = \sum_c \lambda_{ac}^{AC} \\ &= \sum_b \lambda_{bc}^{BC} = \sum_c \lambda_{bc}^{BC} = 0, \\ \sum_a \lambda_{abc}^{ABC} &= \sum_b \lambda_{abc}^{ABC} = \sum_c \lambda_{abc}^{ABC} = 0. \end{aligned}$$

This parameterization, in which every set of parameters sums to zero over each of its subscripts, is called *effect coding*. In effect coding, the λ term denotes the grand mean of $\log m_{abc}$. The one-variable parameters λ_a^A , λ_b^B , and λ_c^C indicate the relative number of cases at the various levels of A , B , and C as deviations from the mean. More precisely, they describe the partial skewness of a variable, that is, the skewness within the combined categories of the other variables. The two-variable interaction terms λ_{ab}^{AB} , λ_{ac}^{AC} , and λ_{bc}^{BC} indicate the strength of the partial association between A and B , A and C , and B and C , respectively. The partial association can be interpreted as the mean association between two variables within the levels of the third variable. And finally, the three-factor interaction parameters λ_{abc}^{ABC} indicate how much the conditional two-variable interactions differ from one another within the categories of the third variable.

Another method to identify the log-linear parameters involves fixing the parameters to zero for one category of A , B , and C , respectively. This parameterization, which is called *dummy coding*, is often used in regression models with nominal regressors.

2 Log-linear Models

Although the expected frequencies under both parameterizations are equal, the interpretation of the parameters is rather different. When effect coding is used, the parameters must be interpreted in terms of deviations from the mean, while under dummy coding, they must be interpreted in terms of deviations from the reference category.

Nonsaturated Models

As mentioned above, in a saturated log-linear model, all possible interaction terms are present. In other words, no *a priori* restrictions are imposed on the model parameters apart from the identifying restrictions. However, in most applications, the aim is to specify and test more parsimonious models, that is, models in which some *a priori* restrictions are imposed on the parameters. Log-linear models in which the parameters are restricted in some way are called *nonsaturated models*. There are different kinds of restrictions that can be imposed on the log-linear parameters. One particular type of restriction leads to the family of hierarchical log-linear models. These are models in which the log-linear parameters are fixed to zero in such a way that when a particular interaction term is fixed to zero, all higher-order interaction terms containing all its indices as a subset must also be fixed to zero. For example, if the partial association between A and B (λ_{ab}^{AB}) is assumed not to be present, the three-variable interaction λ_{abc}^{ABC} must be fixed to zero as well. Applying this latter restriction to (1) results in the following nonsaturated hierarchical log-linear model:

$$\log m_{abc} = \lambda + \lambda_a^A + \lambda_b^B + \lambda_c^C + \lambda_{ac}^{AC} + \lambda_{bc}^{BC}. \quad (3)$$

Another example of a nonsaturated hierarchical log-linear model is the (trivariate) independence model

$$\log m_{abc} = \lambda + \lambda_a^A + \lambda_b^B + \lambda_c^C.$$

Hierarchical log-linear models are the most popular log-linear models because, in most applications, it is not meaningful to include higher-order interaction terms without including the lower-order interaction terms concerned. Another reason is that it is relatively easy to estimate the parameters of hierarchical log-linear models because of the existence of simple minimal sufficient statistics (see **Estimation**).

Other Types of Log-linear Models

General Log-linear Model

So far, attention has been paid to only one special type of log-linear models, the hierarchical log-linear models. As demonstrated, hierarchical log-linear models are based on one particular type of restriction on the log-linear parameters. But, when the goal is to construct models which are as parsimonious as possible, the use of hierarchical log-linear models is not always appropriate. To be able to impose other kinds of linear restrictions on the parameters, it is necessary to use more general kinds of log-linear models.

As shown by McCullagh and Nelder [23], log-linear models can also be defined in a much more general way by viewing them as a special case of the **generalized linear modelling (GLM)** family. In its most general form, a log-linear model can be defined as

$$\log m_i = \sum_j \lambda_j x_{ij}, \quad (4)$$

where m_i denotes a cell entry, λ_j a log-linear parameter, and x_{ij} an element of the design matrix. The design matrix provides us with a very flexible tool for specifying log-linear models with various restrictions on the parameters. For detailed discussions on the use of design matrices in log-linear analysis, see, for example, [10], [14], [15], and [25].

Let us first suppose we want to specify the design matrix for an *hierarchical* log-linear model of the form $\{AB, BC\}$. Assume that A^* , B^* , and C^* , the number of categories of A , B , and C , are equal to 3, 3, and 4, respectively. Because in that case model $\{AB, BC\}$ has 18 independent parameters to be estimated, the design matrix will consist of 18 columns: 1 column for the main effect λ , 7 ($[A^* - 1] + [B^* - 1] + [C^* - 1]$) columns for the one-variable terms λ_a^A , λ_b^B , and λ_c^C , and 10 ($[A^* - 1] * [B^* - 1] + [B^* - 1] * [C^* - 1]$) columns for the two-variable terms λ_{ab}^{AB} and λ_{bc}^{BC} . The exact values of the cells of the design matrix, the x_{ij} , depend on the restrictions which are imposed to identify the parameters. Suppose, for instance, that column j refers to the one-variable term λ_a^A and that the highest level of A , A^* , is used as the (arbitrary) omitted category. In effect coding, the element of the design matrix corresponding to the i th cell, x_{ij} , will equal 1 if $A = a$, -1 if $A = A^*$, and otherwise 0. On

the other hand, in dummy coding, x_{ij} would be 1 if $A = a$, and otherwise 0. The columns of the design matrix referring to the two-variable interaction terms can be obtained by multiplying the columns for the one-variable terms for the variables concerned (see [10] and [14]).

The design matrix can also be used to specify all kinds of *nonhierarchical* and *nonstandard* models. Actually, by means of the design matrix, three kinds of linear restrictions can be imposed on the log-linear parameters: a parameter can be fixed to zero, specified to be equal to another parameter, and specified to be in a fixed ratio to another parameter.

The first kind of restriction, *fixing to zero*, is accomplished by deleting the column of the design matrix referring to the effect concerned. Note that, in contrast to hierarchical log-linear models, parameters can be fixed to be equal to zero without the necessity of deleting the higher-order effects containing the same indices as a subset.

Equating parameters is likewise very simple. Equality restrictions are imposed by adding up the columns of the design matrix which belong to the effects which are assumed to be equal. Suppose, for instance, that we want to specify a model with a symmetric association between the variables A and B ,¹ each having three categories. This implies that

$$\lambda_{ab}^{AB} = \lambda_{ba}^{AB}.$$

The design matrix for the unrestricted effect λ_{ab}^{AB} contains four columns, one for each of the parameters λ_{11}^{AB} , λ_{12}^{AB} , λ_{21}^{AB} , λ_{22}^{AB} . In terms of these four parameters, the symmetric association between A and B implies that λ_{12}^{AB} is assumed to be equal to λ_{21}^{AB} . This can be accomplished by summing the columns of the design matrix referring to these two effects.

As already mentioned above, parameters can also be restricted to be in a *fixed ratio* to each other. This is especially useful when the variables concerned can be assumed to be measured on an ordinal or interval level scale, with known scores for the different categories. Suppose, for instance, that we wish to restrict the one-variable effect of variable A to be linear. Assume that the categories scores of A , denoted by a , are equidistant, that is, that they take on the values 1, 2, and 3. Retaining the effect coding scheme, a linear effect of A is obtained by

$$\lambda_a^A = (a - \bar{a})\lambda^A.$$

Here, $\bar{a}$ denotes the mean of the category scores of A , which in this case is 2. Moreover, λ^A denotes the single parameter describing the one-variable term for A . It can be seen that the distance between the λ_a^A parameters of adjacent categories of A is λ^A . In terms of the design matrix, such a specification implies that instead of including $A^* - 1$ columns for the one-variable term for A , one column with scores $(a - \bar{a})$ has to be included.

These kinds of linear constraints can also be imposed on the bivariate association parameters of a log-linear model. The best known examples are linear-by-linear interaction terms and row- or column-effect models (see [5], [7], [13], and [15]). When specifying a linear-by-linear interaction term, it is assumed that the scores of the categories of both variables are known. Assuming equidistant scores for the categories of the variables A and B and retaining the effect coding scheme, the linear-by-linear interaction between A and B is given by

$$\lambda_{ab}^{AB} = (a - \bar{a})(b - \bar{b})\lambda^{AB}. \quad (5)$$

Using this specification, which is sometimes also called *uniform association*, the (partial) association between A and B is described by a single parameter instead of using $(A^* - 1)(B^* - 1)$ independent λ_{ab}^{AB} parameters. As a result, the design matrix contains only one column for the interaction between A and B consisting of the scores $(a - \bar{a})(b - \bar{b})$.

A row association structure is obtained by assuming the column variable to be linear. When A is the row variable, it is defined as

$$\lambda_{ab}^{AB} = (b - \bar{b})\lambda_a^{AB}.$$

Note that for every value of A , there is a λ_a^{AB} parameter. Actually, there are $(A^* - 1)$ independent row parameters. Therefore, the design matrix will contain $(A^* - 1)$ columns which are based on the scores $(b - \bar{b})$. The column association model is, in fact, identical to the row association model, only the roles of the column and row variable change.

Log-rate Model

The general log-linear model discussed in the previous section can be extended to include an additional

4 Log-linear Models

component, viz., a cell weight ([14] and [19]). The log-linear model with cell weights is given by

$$\log\left(\frac{m_i}{z_i}\right) = \sum_j \lambda_j x_{ij}$$

which can also be written as

$$\begin{aligned} \log m_i &= \log z_i + \sum_j \lambda_j x_{ij}, \\ m_i &= z_i \exp\left(\sum_j \lambda_j x_{ij}\right), \end{aligned}$$

where the z_i are the fixed *a priori* cell weights. Sometimes the vector with elements $\log z_i$ is also called the *offset matrix*.

The specification of a z_i for every cell of the contingency table has several applications. One of its possible uses is in the specification of Poisson regression models that take into account the population size or the length of the observation period. This leads to what is called a *log-rate model*, a model for rates instead of frequency counts ([6] and [14]). A rate is a number of events divided by the size of the population exposed to the risk of having the event.

The weight vector can also be used for taking into account sampling or nonresponse weights, in which case the z_i are equated to the inverse of the sampling weights ([1] and [6]). Another use is the inclusion of *fixed effects* in a log-linear model. This can be accomplished by adding the values of the λ parameters which attain fixed values to the corresponding $\log z_i$'s. The last application I will mention is in the analysis of tables with structural zeros, sometimes also called *incomplete tables* [15]. This simply involves setting the $z_i = 0$ for the structurally zero cells.

Log-multiplicative Model

The log-linear model is one of the GLMs, that is, it is a linear model for the logs of the cell counts in a frequency table. However, extensions of the standard log-linear model have been proposed that imply the inclusion of nonlinear terms, the best known example being the log-multiplicative row-column (RC) association models developed by Goodman [13] and Clogg [5] (see [7]). These RC

association models differ from the association models discussed in section 'General Log-linear Model' in that the row and column scores are not *a priori* fixed, but are treated as unknown parameters which have to be estimated as well. More precisely, a linear-by-linear association is assumed between two variables, given the unknown column and row scores.

Suppose we have a model for a three-way frequency table ABC containing log-multiplicative terms for the relationships between A and B and B and C . This gives the following log-multiplicative model:

$$\begin{aligned} \log m_{abc} &= \lambda + \lambda_a^A + \lambda_b^B + \lambda_c^C + \mu_a^{AB} \phi^{AB} \mu_b^{AB} \\ &\quad + \mu_b^{BC} \phi^{BC} \mu_c^{BC}. \end{aligned} \quad (6)$$

The ϕ parameters describe the strength of the association between the variables concerned. The μ 's are the unknown scores for the categories of the variables concerned. As in standard log-linear models, identifying restrictions have to be imposed on the parameters μ . One possible set of identifying restrictions on the log-multiplicative parameters which was also used by Goodman [13] is:

$$\begin{aligned} \sum_a \mu_a^{AB} &= \sum_b \mu_b^{AB} = \sum_b \mu_b^{BC} = \sum_c \mu_c^{BC} = 0 \\ \sum_a (\mu_a^{AB})^2 &= \sum_b (\mu_b^{AB})^2 = \sum_b (\mu_b^{BC})^2 \\ &= \sum_c (\mu_c^{BC})^2 = 1. \end{aligned}$$

This gives row and column scores with a mean of zero and a sum of squares of one.

On the basis of the model described in (6), both more restricted models and less restricted models can be obtained. One possible restriction is to assume the row and column scores within a particular partial association to be equal, for instance, μ_a^{AB} equal to μ_b^{AB} for all a equal to b . Of course, this presupposes that the number of rows equals the number of columns. Such a restriction is often used in the analysis of mobility tables [22]. It is also possible to assume that the scores for a particular variable are equal for different partial associations [5], for example, $\mu_b^{AB} = \mu_b^{BC}$. Less restricted models may allow for different μ and/or ϕ parameters within the levels of some other variable [5], for example,

different values of μ_a^{AB} , μ_b^{AB} , or ϕ^{AB} within levels of C . To test whether the strength of the association between the variables father's occupation and son's occupation changes linearly with time, Luijkx [22] specified models in which the ϕ parameters are a linear function of time.

As mentioned above, the RC association models assume a linear-by-linear interaction in which the row and column scores are unknown. Xie [31] demonstrated that the basic principle behind Goodman's RC association models, that is, linearly restricting log-linear parameters with unknown scores for the linear terms, can be applied to any kind of log-linear parameter. He proposed a general class of log-multiplicative models in which higher-order interaction terms can be specified in a parsimonious way.

Regression-, Path-, and Factor-analytic Models

Log-linear Regression Analysis: the Logit Model

In the log-linear models discussed so far, the relationships between the categorical variables are modeled without making a priori assumptions about their 'causal' ordering: no distinction is made between dependent and independent variables. However, one is often interested in predicting the value of a categorical response variable by means of explanatory variables. The logit model is such a 'regression analytic' model for a categorical dependent variable.

Suppose we have a response variable denoted by C and two categorical explanatory variables denoted by A and B . Moreover, assume that both A and B influence C , but that their effect is equal within levels of the other variable. In other words, it is assumed that there is no interaction between A and B with respect to their effect on C . This gives the following logistic model for the conditional probability of C given A and B , $\pi_{c|ab}$:

$$\pi_{c|ab} = \frac{\exp(\lambda_c^C + \lambda_{ac}^{AC} + \lambda_{bc}^{BC})}{\sum_c \exp(\lambda_c^C + \lambda_{ac}^{AC} + \lambda_{bc}^{BC})}. \quad (7)$$

When the response variable C is dichotomous, the logit can also be written as

$$\log\left(\frac{\pi_{1|ab}}{1 - \pi_{1|ab}}\right) = \log\left(\frac{\pi_{1|ab}}{\pi_{2|ab}}\right)$$

$$\begin{aligned} &= (\lambda_1^C - \lambda_2^C) + (\lambda_{a1}^{AC} - \lambda_{a2}^{AC}) \\ &\quad + (\lambda_{b1}^{BC} - \lambda_{b2}^{BC}) \\ &= \beta + \beta_a^A + \beta_b^B. \end{aligned}$$

It should be noted that the logistic form of the model guarantees that the probabilities remain in the admissible interval between 0 and 1.

It has been shown that a logit model is equivalent to a log-linear model which not only includes the same λ terms, but also the effects corresponding to the marginal distribution of the independent variables ([1], [11], [14]). For example, the logit model described in (7) is equivalent to the following log-linear model

$$\log m_{abc} = \alpha_{ab}^{AB} + \lambda_c^C + \lambda_{ac}^{AC} + \lambda_{bc}^{BC}, \quad (8)$$

where

$$\alpha_{ab}^{AB} = \lambda + \lambda_a^A + \lambda_b^B + \lambda_{ab}^{AB}.$$

In other words, it equals log-linear model $\{AB, AC, BC\}$ for the frequency table with expected counts m_{abc} . With polytomous response variables, the log-linear or logit model of the form given in (8) is sometimes referred to as a multinomial response model. As shown by Haberman [15], in its most general form, the multinomial response model may be written as

$$\log m_{ik} = \alpha_k + \sum_j \lambda_j x_{ijk}, \quad (9)$$

where k is used as the index for the joint distribution of the independent variables and i as an index for the response variable.

Log-linear Path Analysis

After presenting a 'regression analytic' extension, we will now discuss a 'path-analytic' extension of log-linear analysis introduced by Goodman [12]. As is shown below, his 'modified **path analysis** approach' that makes it possible to take into account information on the causal and/or time ordering between the variables involves specifying a series of logit models.

Figure 1 Modified path model

Suppose we want to investigate the causal relationships between six categorical variables denoted by A , B , C , D , E , and F . Figure 1 shows the assumed causal ordering and relationships between these variables, where a pointed arrow indicates that variables are directly related to each other, and a ‘knot’ that there is a higher-order interaction. The variables A , B , and C are exogenous variables. This means that neither their mutual causal order nor their mutual relationships are specified. The other variables are endogenous variables, where E is assumed to be posterior to D , and F is assumed to be posterior to E . From Figure 1, it can be seen that D is assumed to depend on A and on the interaction of B and C . Moreover, E is assumed to depend on A , B , and D , and F on B , C , D , and E .

Let $\pi_{def|abc}$ denote the probability that $D = d$, $E = e$, and $F = f$, given $A = a$, $B = b$, and $C = c$. The information on the causal ordering of the endogenous variables is used to decompose this probability into a product of marginal conditional probabilities ([12] and [30]). In this case, $\pi_{def|abc}$ can also be written as

$$\pi_{def|abc} = \pi_{d|abc} \pi_{e|abcd} \pi_{f|abcde}. \quad (10)$$

This is a straightforward way to indicate that the value on a particular variable can only depend on the preceding variables and not on the posterior ones. For instance, E is assumed to depend only on the preceding variables A , B , C , and D , but not on the posterior variable F . Therefore, the probability that $E = e$ depends only on the values of A , B , C , and D , and not on the value of F .

Decomposing the joint probability $\pi_{def|abc}$ into a set of marginal conditional probabilities is only the first step in describing the causal relationships

between the variables under study. In fact, the model given in (10) is still a saturated model in which it is assumed that a particular dependent variable depends on all its posterior variables, including all the higher-order interaction terms. A more parsimonious specification is obtained by using a log-linear or logit parameterization for the conditional probabilities appearing in (10) [12]. While only simple hierarchical log-linear models will be here used, the results presented apply to other kinds of log-linear models as well, including the log-multiplicative models discussed in section ‘Log-multiplicative Model’.

A system of logit models consistent with the path model depicted in Figure 1 leads to the following parameterization of the conditional probabilities appearing in (10):

$$\begin{aligned} \pi_{d|abc} &= \frac{\exp(\lambda_d^D + \lambda_{ad}^{AD} + \lambda_{bd}^{BD} + \lambda_{cd}^{CD} + \lambda_{bcd}^{BCD})}{\sum_d \exp(\lambda_d^D + \lambda_{ad}^{AD} + \lambda_{bd}^{BD} + \lambda_{cd}^{CD} + \lambda_{bcd}^{BCD})}, \\ \pi_{e|abcd} &= \frac{\exp(\lambda_e^E + \lambda_{ae}^{AE} + \lambda_{be}^{BE} + \lambda_{de}^{DE})}{\sum_e \exp(\lambda_e^E + \lambda_{ae}^{AE} + \lambda_{be}^{BE} + \lambda_{de}^{DE})}, \\ \pi_{f|abcde} &= \frac{\exp(\lambda_f^F + \lambda_{bf}^{BF} + \lambda_{cf}^{CF} + \lambda_{df}^{DF} + \lambda_{ef}^{EF})}{\sum_f \exp(\lambda_f^F + \lambda_{bf}^{BF} + \lambda_{cf}^{CF} + \lambda_{df}^{DF} + \lambda_{ef}^{EF})}. \end{aligned}$$

As can be seen, variable D depends on A , B , and C , and there is a three-variable interaction between B , C , and D ; E depends on A , B , and D , but there are no higher-order interactions between E and the independent variables; and F depends on B , C , D , and E .

Log-linear Factor Analysis: the Latent Class Model

As many concepts in the social sciences are difficult or impossible to measure directly, several directly observable variables, or indicators, are often used as indirect measures of the concept to be measured. The values of the indicators are assumed to be determined only by the unobservable value of the underlying variable of interest and by measurement error. In latent structure models, this principle is implemented statistically by assuming probabilistic

relationships between latent and manifest variables and by the assumption of local independence. Local independence means that the indicators are assumed to be independent of each other given a particular value of the unobserved or latent variable; in other words, they are only correlated because of their common cause (*see Conditional Independence*).

Latent structure models can be classified according to the measurement level of the latent variable(s) and the measurement level of the manifest variables. When both the latent and observed variables are categorical, one obtains a model called latent class model. As shown by Haberman [15], the latent class model can be defined as a log-linear model with one or more unobserved variables, yielding a ‘factor-analytic’ variant of the log-linear model.

Suppose there is, as depicted in Figure 2, a latent class model with one latent variable W with index w and 4 indicators A , B , C , and D with indices a , b , c , and d . Moreover, let W^* denote the number of latent classes. This latent class model is equivalent to the hierarchical log-linear model $\{WA, WB, WC, WD\}$; that is,

$$\log m_{abcd} = \lambda + \lambda_w^W + \lambda_a^A + \lambda_b^B + \lambda_c^C + \lambda_d^D + \lambda_{wa}^{WA} + \lambda_{wb}^{WB} + \lambda_{wc}^{WC} + \lambda_{wd}^{WD}. \quad (11)$$

In addition to the overall mean and the one-variable terms, it contains only the two-variable associations between the latent variable W and the manifest variables. As none of the interactions between the manifest variables are included, it can be seen that they are assumed to be conditionally independent of each other given W .

Figure 2 Latent class model

In its classical parameterization proposed by Lazarsfeld [21], the latent class model is defined as

$$\pi_{wabcd} = \pi_w \pi_{a|w} \pi_{b|w} \pi_{c|w} \pi_{d|w}. \quad (12)$$

It can be seen that again the observed variables A , B , C , and D are postulated to be mutually independent given a particular score on the latent variable W . Note that this is in fact a log-linear path model in which one variable is unobserved. The relation between the conditional probabilities appearing in (12) and the log-linear parameters appearing in (11) is

$$\pi_{a|w} = \frac{\exp(\lambda_a^A + \lambda_{wa}^{WA})}{\sum_a \exp(\lambda_a^A + \lambda_{wa}^{WA})}. \quad (13)$$

Estimation, Testing, and Software

Maximum Likelihood Estimation

Maximum likelihood (ML) estimates for the expected frequencies of a specific log-linear model are most easily derived assuming a Poisson sampling scheme (*see Catalogue of Probability Density Functions*), but the same estimates are obtained with a multinomial or product-multinomial sampling scheme. Denoting an observed frequency in a three-way table by n_{abc} , the relevant part of the Poisson log-likelihood function is

$$\log \mathcal{L} = \sum_{abc} (n_{abc} \log m_{abc} - m_{abc}), \quad (14)$$

where the expected frequencies m_{abc} are a function of the unknown λ parameters.

Suppose we want to find ML estimates for the parameters of the hierarchical log-linear model described in (3). Substituting (3) into (14) and collapsing the cells containing the same λ parameter, yields the following log-likelihood function:

$$\begin{aligned} \log \mathcal{L} = & n_{+++} \lambda + \sum_a n_{a++} \lambda_a^A + \sum_b n_{+b+} \lambda_b^B \\ & + \sum_c n_{++c} \lambda_c^C + \sum_{ab} n_{ab+} \lambda_{ab}^{AB} \\ & + \sum_{bc} n_{+bc} \lambda_{bc}^{BC} - \sum_{abc} \exp(u + \lambda_a^A + \lambda_b^B \\ & + \lambda_c^C + \lambda_{ab}^{AB} + \lambda_{bc}^{BC}), \end{aligned} \quad (15)$$

where a $+$ is used as a subscript to denote that the observed frequencies have to be collapsed over the dimension concerned. It can now be seen that the observed marginals n_{+++} , n_{a++} , n_{+b+} , n_{++c} , n_{ab+} , and n_{+bc} contain all the information needed to estimate the unknown parameters. Because knowledge of the bivariate marginals AB and BC implies knowledge of n_{+++} , n_{a++} , n_{+b+} , and n_{++c} , n_{ab+} and n_{+bc} are called *the minimal sufficient statistics*, the minimal information needed for estimating the log-linear parameters of the model of interest.

In hierarchical log-linear models, the minimal sufficient statistics are always the marginals corresponding to the interaction terms of the highest order. For this reason, hierarchical log-linear models are mostly denoted by their minimal sufficient statistics. The model given in (3) may then be denoted as $\{AB, BC\}$, the independence model as $\{A, B, C\}$, and the saturated model as $\{ABC\}$.

When no closed form expression exists for $\hat{m}_{abc}$, ML estimates for the expected cell counts can be found by means of the iterative proportional fitting algorithm (IPF) [8]. Let $\hat{m}_{abc}^{(v)}$ denote the estimated expected frequencies after the v th IPF iteration. Before starting the first iteration, arbitrary starting values are needed for the log-linear parameters that are in the model. In most computer programs based on the IPF algorithm, the iterations are started with all the λ parameters equal to zero, in other words, with all estimated expected frequencies $\hat{m}_{abc}^{(0)}$ equal to 1. For the model in (3), every IPF iteration consists of the following two steps:

$$\hat{m}_{abc}^{(v)'} = \hat{m}_{abc}^{(v-1)} \frac{n_{ab+}}{\hat{m}_{ab+}^{(v-1)}},$$

$$\hat{m}_{abc}^{(v)} = \hat{m}_{abc}^{(v)'} \frac{n_{+bc}}{\hat{m}_{+bc}^{(v)'}},$$

where the $\hat{m}_{abc}^{(v)'}$ and $\hat{m}_{abc}^{(v)}$ denote the improved estimated expected frequencies after imposing the ML related restrictions. The log-linear parameters are easily computed from the estimated expected frequencies.

Finding ML estimates for the parameters of other types of log-linear models is a bit more complicated than for the hierarchical log-linear model because the sufficient statistics are no longer equal to particular observed marginals. Most programs solve this problem using a *Newton-Raphson algorithm*. An alternative to

the Newton-Raphson algorithm is the *unidimensional Newton algorithm*. It differs from the multidimensional Newton algorithm in that it adjusts only one parameter at a time instead of adjusting them all simultaneously. In that sense, it resembles IPF. Goodman [13] proposed using the unidimensional Newton algorithm for the estimation of log-multiplicative models.

For ML estimation of latent class models, one can make use of an IPF-like algorithm called the *Expectation-Maximization* (EM) algorithm, a Newton-Raphson algorithm, or a combination of these (see **Maximum Likelihood Estimation; Optimization Methods**).

Model Selection

The goodness of fit of a postulated log-linear model can be assessed by comparing the observed frequencies, n , with the estimated expected frequencies, $\hat{m}$. For this purpose, usually two chi-square statistics are used: the likelihood-ratio statistic and the Pearson statistic. For a three-way table, the Pearson chi-square statistic equals

$$X^2 = \sum_{abc} \frac{(n_{abc} - \hat{m}_{abc})^2}{\hat{m}_{abc}},$$

and the likelihood-ratio chi-square statistic is

$$L^2 = 2 \sum_{abc} n_{abc} \log \left(\frac{n_{abc}}{\hat{m}_{abc}} \right). \quad (16)$$

The number of degrees of freedom for a particular model is

df = number of cells

– number of independent u parameters.

Both chi-square statistics have asymptotic, or large sample, chi-square distributions when the postulated model is true. In the case of small sample sizes and sparse tables, the chi-square approximation will generally be poor. Koehler [18] showed that X^2 is valid with smaller sample sizes and sparser tables than L^2 and that the distribution of L^2 is usually poor when the sample size divided by the number of cells is less than 5. Therefore, when sparse tables are analyzed, it is best to use both chi-square

statistics together. When X^2 and L^2 have almost the same value, it is more likely that both chi-square approximations are good. Otherwise, at least one of the two approximations is poor.²

The likelihood-ratio chi-square statistic is actually a conditional test for the significance of the difference in the value of the log-likelihood function for two nested models. Two models are nested when the restricted model has to be obtained by only linearly restricting some parameters of the unrestricted model. Thus, the likelihood-ratio statistic can be used to test the significance of the additional free parameters in the unrestricted model, given that the unrestricted model is true in the population. Assuming multinomial sampling, L^2 can be written more generally as

$$\begin{aligned} L^2_{(r|u)} &= (-2 \log \mathcal{L}_{(r)}) - (-2 \log \mathcal{L}_{(u)}) \\ &= 2 n_{abc} \log \hat{\pi}_{abc(u)} - 2 n_{abc} \log \hat{\pi}_{abc(r)} \\ &= 2 n_{abc} \log \left(\frac{\hat{m}_{abc(u)}}{\hat{m}_{abc(r)}} \right), \end{aligned}$$

where the subscript (u) refers to the unrestricted model and the subscript (r) to the restricted model. Note that in (16), a particular model is tested against the completely unrestricted model, the saturated model. Therefore, in (16), the estimated expected frequency in the numerator is the observed frequency n_{abc} . The $L^2_{(r|u)}$ statistic has a large sample chi-square distribution if the restricted model is approximately true. The approximation of the chi-square distribution may be good for conditional L^2 tests between non-saturated models even if the test against the saturated model is problematic, as in sparse tables. The number of degrees of freedom in conditional tests equals the number of parameters which are fixed in the restricted model compared to the unrestricted model. The $L^2_{(r|u)}$ statistic can also be computed from the unconditional L^2 values of two nested models,

$$L^2_{(r|u)} = L^2_{(r)} - L^2_{(u)},$$

with

$$\text{df}_{(r|u)} = \text{df}_{(r)} - \text{df}_{(u)}.$$

Another approach to model selection is based on information theory. The aim is not to detect the true model but the model that provides the most information about the real world. The best known information criteria are the **Akaike information**

criterion (AIC) [3] and the Schwarz [26] or bayesian information criterion (BIC). These two measures, which can be used to compare both nested and nonnested models, are usually defined as

$$AIC = L^2 - 2 \text{df}. \quad (17)$$

$$BIC = L^2 - \log N \text{df}. \quad (18)$$

Software

Software for log-linear analysis is readily available. Major statistical packages such as SAS and SPSS have modules for log-linear analysis that can be used for estimating hierarchical and general log-linear models, log-rate models, and logit models. Special software is required for estimating log-multiplicative models, log-linear path models, and latent class models. The command language based ℓ_{EM} program developed by Vermunt [27], [28] can deal with any of the models discussed in this article, as well as combinations of these. Vermunt and Magidson's [29] Windows based Latent GOLD can deal with certain types of log-linear models, logit models, and latent class models, as well as combinations of logit and latent class models.

An Application

Consider the four-way cross-tabulation presented in Table 1 containing data taken from four annual waves (1977–1980) of the National Youth Survey [9]. The table reports information on marijuana use of 237 respondents who were age 14 in 1977. The variable of interest is an ordinal variable measuring marijuana use in the past year. It has the three levels ‘never’ (1), ‘no more than once a month’ (2), and ‘more than once a month’ (3). We will denote these four time-specific measures by A , B , C , and D , respectively.

Several types of log-linear models are of interest for this data set. First, we might wish to investigate the overall dependence structure of these repeated responses, for example, whether it is possible to describe the data by a hierarchical log-linear model containing only the two-way associations between consecutive time points; that is, by a first-order Markov structure. Second, we might want to investigate whether it is possible to simplify the model by making use of the ordinal nature of the variables using uniform or RC association structures.

Table 1 Data on marijuana use in the past year taken from four yearly waves of the National Youth Survey (1977–1980)

1977 (A)	1978 (B)	1979 (C)								
		1			2			3		
		1980 (D)			1980 (D)			1980 (D)		
		1	2	3	1	2	3	1	2	3
1	1	115	18	7	6	6	1	2	1	5
1	2	2	2	1	5	10	2	0	0	6
1	3	0	1	0	0	1	0	0	0	4
2	1	1	3	0	1	0	0	0	0	0
2	2	2	1	1	2	1	0	0	0	3
2	3	0	1	0	0	1	1	0	2	7
3	1	0	0	0	0	0	0	0	0	1
3	2	1	0	0	0	1	0	0	0	1
3	3	0	0	0	0	2	1	1	1	6

Table 2 Goodness-of-fit statistics for the estimated models for the data in Table 1

Model	L^2	df	$\hat{p}$	AIC
1. Independence	403.3	72	.00	259.3
2. All two-variable terms	36.9	48	.12	−59.1
3. First-order Markov	58.7	60	.05	−61.3
4. Model 3 + $\lambda_{j\ell}^{BD}$	41.6	56	.30	−70.4
5. Model 4 with uniform associations	83.6	68	.00	−52.4
6. Two-class latent class model	126.6	63	.00	−51.0
7. Three-class latent class model	57.0	54	.12	−56.2

Third, latent class analysis could be used to determine whether it is possible to explain the associations by assuming that there is a small number of groups of children with similar developments in marijuana use.

Table 2 reports the L^2 values for the estimated models. Because the asymptotic P values are unreliable when analyzing sparse frequency tables such as the one we have here, we estimated the P values by means of 1000 parametric bootstrapping replications. The analysis was performed with the Latent GOLD program.

The high L^2 value obtained with Model 1 – the independence model $\{A, B, C, D\}$ – indicates that there is a strong dependence between the 4 time-specific measures. Model 2 is the model with all two-variable associations: $\{AB, AC, AD, BC, BD, CD\}$. As can be seen from its P value, it fits very well, which indicates that higher-order interactions are not needed. The Markov model containing only

associations between adjacent time points – Model 3: $\{AB, BC, CD\}$ – seems to be too restrictive for this data set. It turns out that we need to include one additional term; that is, the association between the second and fourth time point, yielding $\{AB, BC, BD, CD\}$ (Model 4).

Model 5 has the same structure as Model 4, with the only difference that the two-variable terms are assumed to be uniform associations (see 5). This means that each two-way association contains only one instead of four independent parameters. These ‘ordinal’ constraints seems to be too restrictive for this data set.

Models 6 and 7 are latent class models or, equivalently, log-linear models of the form $\{XA, XB, XC, XD\}$, where X is a latent variable with either two or three categories. The fit measures indicate that the associations between the time points can be explained by the existence of three types of trajectories of marijuana use.

Based on the comparison of the goodness of fit measures for the various models, as well as their AIC values that also take into account parsimony, one can conclude that Model 4 is the preferred one. The three-class, however, yields a somewhat simpler explanation for the associations between the time-specific responses.

Notes

1. Log-linear models with symmetric interaction terms may be used for various purposes. In longitudinal research, they may be applied to test the assumption of marginal homogeneity (see [1] and [16]). Other applications of log-linear models with symmetric association parameters are Rasch models for dichotomous (see [24] and [17]) and polytomous items (see [2]).
2. An alternative approach is based on estimating the sampling distributions of the statistics concerned rather than using their asymptotic distributions. This can be done by bootstrap methods [20]. These computationally intensive methods are becoming more and more applicable as computers become faster.

Log-linear Rasch Models for Stability and Change

The latent trait model proposed by Georg Rasch [18, 19] specifies the probability that a person gives the correct response to a test item as a function of the person's ability and the item's difficulty:

$$p(X_{vi} = 1 | \theta_v, \beta_i) = \frac{\exp(\theta_v - \beta_i)}{1 + \exp(\theta_v - \beta_i)} \quad (1)$$

In the equation, $X_{vi} = 1$ means that item i is successfully solved by person v , θ_v denotes the ability parameter of person v , and β_i denotes the difficulty parameter of item i . The logistic function in (1) leads to the s-shaped item characteristic curve displayed in Figure 1. The item characteristic curve shows the probability to solve a given item i with its difficulty parameter β_i for varying ability parameters θ . As illustrated in Figure 1, the probability is 0.5 if the ability parameter θ equals the item's difficulty parameter β_i . For smaller values of θ , the probability to solve the item steadily descends to its lower asymptote of 0. At the other extreme, for larger values of θ , the probability ascends to its upper asymptote of 1.

Rasch Models for Longitudinal Data

The Rasch model can be used to measure latent traits like abilities or attitudes at a given point in time. Aside from the measurement of latent constructs at one occasion (see **Latent Class Analysis**), Rasch

Figure 1 Item characteristic curve of the Rasch model

models also allow one to analyze change in longitudinal research designs (see **Longitudinal Data Analysis**), in which the same items are repeatedly administered. A simple extension of the Rasch model to longitudinal data follows from the assumption of *global change* [7, 22]:

$$p(X_{vit} = 1 | \theta_v, \beta_i, \lambda_t) = \frac{\exp(\theta_v + \lambda_t - \beta_i)}{1 + \exp(\theta_v + \lambda_t - \beta_i)} \quad (2)$$

In (2), X_{vit} denotes the response of person v to item i at occasion t , and the new parameter λ_t reflects the change on the latent dimension that has occurred until occasion t , with $\lambda_1 = 0$. Because the change parameter λ_t is independent of person v and item i , the model specifies a global change process that is homogeneous across persons and items. Homogeneity of change across persons means that all persons move on the latent continuum in the same direction and by the same amount. As a consequence, interindividual differences in the latent trait θ are preserved over time. Figure 2 illustrates homogeneity of change and the resulting stability of interindividual differences. The figure depicts the probability to solve an item with given difficulty parameter for two persons with initial values θ_1 and θ_2 on the latent trait continuum. As indicated in the figure, the difference between the two persons remains constant for any given change parameter λ_t .

Figure 2 Global change on the latent trait continuum with preservation of interindividual differences. Solid lines symbolize the first measurement occasion and dashed lines symbolize the second measurement occasion

2 Log-linear Rasch Models

The rather restrictive assumption of homogeneous change across persons can be dropped by specifying different person parameters for different occasions [1, 22]:

$$p(X_{vit} = 1 | \theta_{vt}, \beta_i) = \frac{\exp(\theta_{vt} - \beta_i)}{1 + \exp(\theta_{vt} - \beta_i)} \quad (3)$$

Here, the latent trait parameter θ_{vt} reflects an interaction of person v and occasion t , so that the model permits *person-specific change*. Formally, (3) presents a multidimensional latent trait model, because it contains one latent trait dimension for each of t occasions. As a consequence, the model allows for differences in the latent trait between persons at each occasion, and these interindividual differences may vary over time.

Log-linear Representation of Rasch Models for the Analysis of Change

The expected probabilities of response vectors under the Rasch model can be represented by **log-linear models** [5, 11]. The log-linear model formulation facilitates flexible hypothesis tests, which makes it particularly suitable for the analysis of latent change [14, 17].

Imagine that a set of I items is applied at two measurement occasions and that $X_{i1} = 1$ denotes a correct response to item i at the first occasion, whereas $X_{i1} = 0$ denotes an incorrect response. Likewise, let $X_{i2} = 1$ and $X_{i2} = 0$ mean success and failure, respectively, with respect to item i at the second occasion. Then $\mathbf{X} = (X_{11}, \dots, X_{I1}, X_{12}, \dots, X_{I2})$ is the response vector of zeros and ones referring to the I items at the two occasions. Under the Rasch model of global change defined in (2), the logarithm of the probability of a given response vector can be written as [14, 16]

$$\begin{aligned} \ln p(\mathbf{X} = (x_{11}, \dots, x_{I1}, x_{12}, \dots, x_{I2})) \\ = u - \sum_{j=1}^2 \sum_{i=1}^I x_{ij} \beta_i + \sum_{i=1}^I x_{i2} \lambda_2 + u_s. \end{aligned} \quad (4)$$

The parameter u denotes the overall constant, and u_s is an additional constant for all response vectors with total score s , that is, for all $\mathbf{x}$ with $\sum_j \sum_i x_{ij} = s$. The total score parameter s is the sufficient statistic for person parameter θ and carries all the

information about θ from the response vector [2, 6]. Therefore, (4) specifies the logarithm of the expected probability of the response vector across two occasions in terms of a linear combination of the two constants, the set of item parameters, and the change parameter.

Analogously, the probabilities of response vectors under the Rasch model of person-specific change defined in (3) can be represented by a log-linear model of the form

$$\begin{aligned} \ln p(\mathbf{X} = (x_{11}, \dots, x_{I1}, x_{12}, \dots, x_{I2})) \\ = u - \sum_{j=1}^2 \sum_{i=1}^I x_{ij} \beta_i + u_{(s_1, s_2)} \end{aligned} \quad (5)$$

[14, 16]. The term $u_{(s_1, s_2)}$ specifies a constant for all response vectors with total score s_1 at the first occasion and total score s_2 at the second occasion, that is, for all $\mathbf{x}$ with $\sum_i x_{i1} = s_1$ and $\sum_i x_{i2} = s_2$. The combination of total scores s_1 and s_2 is the sufficient statistic for the combination of latent traits θ_1 and θ_2 concerning the first and second occasion. Therefore, the logarithm of the expected probability of a given response vector can be written as a linear combination of the constant terms and the item parameters.

The log-linear representation of Rasch models facilitates the specification and test of hypotheses about change. For instance, the occurrence of global change can be tested by comparing the full log-linear model in (4) with a restricted version that contains the parameter fixation $\lambda_2 = 0$. As the fixation implies that there is no change in the latent trait from the first to the second occasion, a significant difference between the full model and the restricted model indicates that global change takes place. In a similar vein, a statistical comparison between the log-linear model of global change in (4) and the log-linear model of person-specific change in (5) may be used to test for homogeneity of change across persons. The model of person-specific change includes the model of global change as a special case, because setting $u_{(s_1, s_2)} = u_{(s_1 + s_2)} + s_2 \cdot \lambda$ in (5) yields (4) [14, 16]. Hence, a significant difference between the two models indicates that the homogeneity assumption is violated and that change is person specific. Such testing options can be used to investigate the course of development in longitudinal research as well as to analyze the effectiveness of intervention programs in evaluation studies.

Identifiability, Parameter Estimation, and Model Testing

Equations (4) and (5) specify nonstandard log-linear models, which can be presented in terms of their design matrices and parameter vectors (see [4, 20]). Let μ be the vector of expected probabilities and $\mathbf{B}$ the vector of model parameters. Then the design matrix $\mathbf{M}$ defines the linear combination of model parameters for each expected probability, such that $\mu = \mathbf{MB}$. The model parameters are identifiable if $\mathbf{M}$ is of full rank. To achieve identifiability, restrictions have to be imposed on the log-linear parameters in (4) and (5). Appropriate restrictions follow from the common constraints that the item parameters and the total score parameters sum to zero, that is, $\sum_i \beta_i = 0$, $\sum_s u_s = 0$ and $\sum_{s_1} \sum_{s_2} u_{(s_1, s_2)} = 0$.

Nonstandard log-linear models like the Rasch models in (4) and (5) can be implemented in statistical programs which allow user-defined design matrices, such as SAS or LEM [23] (see **Structural Equation Modeling: Software**). These programs provide **maximum likelihood estimates** of the parameters and **goodness-of-fit** indices for the model. The goodness of fit of a log-linear model can be tested by means of the likelihood ratio statistic G^2 , which asymptotically follows a χ^2 distribution [2, 3]. The number of degrees of freedom equals the number of response vectors minus the number of model parameters. If two nonstandard log-linear models are hierarchically nested, then the two models can be compared using the conditional likelihood ratio statistic ΔG^2 . Two models are said to be hierarchically nested if the model with fewer parameters can be derived from the other model by a set of parameter restrictions. If such a hierarchical relation exists, ΔG^2 can be computed as the difference of the likelihood ratios of the two models. The number of degrees of freedom for the model comparison equals the difference in the number of parameters between the two models.

An Empirical Example

The use of log-linear Rasch models for the analysis of change can be illustrated by a recent reanalysis of data from the longitudinal SCHOLASTIK study [16]. The SCHOLASTIK study assessed children at several elementary schools in Germany with various

performance measures from first through fourth grade [25]. The reanalysis with log-linear Rasch models focused on the responses of $N = 1030$ children to specific kinds of arithmetic word problems applied in second and third grade. Figure 3 shows the relative frequencies of correct solutions to three arithmetic items. The log-linear Rasch model of homogeneous change (see (4)) yielded a significant parameter of global learning from Grade 2 to Grade 3 for these items, $\hat{\lambda} = 0.669$. Moreover, differences in item difficulty were indicated by the estimated item parameters. Mirroring the relative frequencies of correct solutions in Figure 3, Item 1 was the least difficult item, $\hat{\beta}_1 = -0.244$, Item 2 was the most difficult item, $\hat{\beta}_2 = 0.310$, and Item 3 fell in between the other two, $\hat{\beta}_3 = -0.066$.

However, the model of global change provided only a poor goodness of fit to the empirical data, $G^2(54) = 72.53$, $p = 0.047$, suggesting that the homogeneity assumption may be violated. The less restrictive model of person-specific change (see (5)) fitted the data well, $G^2(46) = 54.84$, $p = 0.175$. In fact, a statistical comparison of the two models indicated that the model of person-specific change shows a significantly better fit than the model of homogeneous change, $\Delta G^2(8) = 17.69$, $p = 0.024$. We may thus conclude that there are not only interindividual differences in the ability to solve arithmetic problems, but that the children also differ in their speed of development from Grade 2 to Grade 3.

Figure 3 Relative frequencies of correct responses to three arithmetic word problems at two measurement occasions

Model Extensions

The models described in this entry can easily be extended to more than two measurement occasions and in various other ways. First, if effects of different treatments are to be compared in an experimental or quasi-experimental design, a grouping variable can be introduced that allows one to test for differences in the change parameter λ as a function of treatment group [7]. Second, generalizations of the Rasch model to polytomous items with more than two response categories have been adopted for the measurement of change [8–10]. Third, the log-linear representation of Rasch models was extended to models for the simultaneous measurement of more than one latent trait [12]. Accordingly, log-linear Rasch models of global and person-specific change can be formulated that include several ordered response categories per item and multidimensional latent constructs at each measurement occasion [14, 16].

Furthermore, model extensions in terms of mixture distribution models [13] appear especially useful for the analysis of change. Mixture distribution Rasch models extend the Rasch model by specifying several latent subpopulations that may differ with respect to the model parameters [21, 24]. While parameter homogeneity is maintained within each latent subpopulation, heterogeneity is admitted between subpopulations. Applied to longitudinal designs, mixture distribution Rasch models can be used to uncover different developmental trajectories in a population by means of subpopulation-specific change parameters [15]. In addition, *a priori* assumptions about differences in change can be specified by parameter restrictions for the latent subpopulations.

To illustrate the use of mixture distribution Rasch models in the analysis of change, we continued the above empirical example of arithmetic problems in elementary school. Because the assumption of homogeneity of change did not hold, one may surmise that there are two subpopulations of children: one subpopulation of children who profit from the training at school and improve their performance from Grade 2 to Grade 3, and a second subpopulation of children whose performance remains unchanged from Grade 2 to Grade 3. We tested this conjecture by means of a mixture distribution model with two subpopulations [16]. For each subpopulation, a Rasch model of homogeneous change (see (2) and (4)) was specified, and in one of the subpopulations the change

parameter was fixed at zero. The resulting ‘mover-stayer Rasch model’ fitted the empirical data well and provided a parsimonious account of the observed heterogeneity of change.

Longitudinal Data Analysis

The distinguishing feature of a longitudinal study is that the response variable of interest and a set of explanatory variables (covariates) are measured repeatedly over time. The main objective in such a study is to characterize change in the response variable over time and to determine the covariates most associated with any change. Because observations of the response variable are made on the same individual at different times, it is likely that the repeated responses for the same person will be correlated with each other (*see* **Clustered Data**). This correlation must be taken into account to draw valid and efficient inferences about parameters of scientific interest. It is the likely presence of such correlation that makes modeling longitudinal data more complex than dealing with a single response for each individual. (Time to event data is also thus a form of longitudinal data – *see* **Event History Analysis**; **Survival Analysis**.)

An Example of a Longitudinal Study

Despite the possible complications of analysis, longitudinal studies are popular in psychology and other disciplines since they allow for understanding the development and persistence of behavior or disease and for identifying factors that can alter the course of either one (*see* **Clinical Trials and Intervention Studies**). For example, readers of this article are unlikely to need to be reminded that depression is a major public health problem across the world. Antidepressants are the frontline treatment, but many patients either do not respond to them or do not like taking them. The main alternative is psychotherapy, and the modern ‘talking treatments’ such as cognitive behavioral therapy (CBT) have been shown to be as effective as drugs, and probably more so when it comes to relapse [5]. But there is a problem, namely, availability – there are not enough skilled therapists to meet the demand, and little prospect at all of this situation changing. A number of alternative modes of delivery of CBT have been explored, including interactive systems making use of the new computer technologies. The principles of CBT lend themselves

reasonably well to computerization, and, perhaps surprisingly, patients adapt well to this procedure, and do not seem to miss the physical presence of the therapist as much as one might expect. One such attempt at computerization, known as ‘Beating the Blues (BtB)’, is described in detail in [4]. But, in essence, BtB is an interactive program using multimedia techniques, in particular, video vignettes. The computer-based intervention consists of nine sessions, followed by eight therapy sessions, each lasting about 50 minutes. Nurses are used to explain how the program works, but are instructed to spend no more than 5 minutes with each patient at the start of each session, and are there simply to assist with the technology. In a randomized controlled trial of the program, patients with depression recruited in primary care were randomized to either the BtB program, or to ‘Treatment as Usual (TAU)’. Patients randomized to BtB also received pharmacology and/or general GP support and practical/social help, offered as part of treatment as usual, with the exception of any face-to-face counseling or psychological intervention. Patients allocated to TAU received whatever treatment their GP prescribed. The latter included, besides any medication, discussion of problems with GP, provision of practical/social help, referral to a counselor, referral to a practice nurse, referral to mental health professionals (psychologist, psychiatrist, community psychiatric nurse, counselor), or further physical examination.

A number of outcome measures were used in the trial, with the primary response being the *Beck Depression Inventory II* – [1]. Measurements on this variable were made on the following five occasions:

- prior to treatment;
- two months after treatment began;
- at one, three, and six months follow-up, that is, at three, five, and eight months after treatment.

The data collected in this study have the following features that are fairly typical of the data collected in many clinical trials and intervention studies in psychiatry and psychology:

- there are a considerable number of **missing values** caused by patients dropping out of the study (*see* **Dropouts in Longitudinal Data**; **Dropouts in Longitudinal Studies: Methods of Analysis**);
- there are repeated measurements of the outcome taken on each patient posttreatment, along with a baseline pretreatment measurement;

2 Longitudinal Data Analysis

- the data is multicenter in that they have been collected from a number of different GP surgeries.

Here, the investigator is primarily interested in assessing the effect of treatment on the repeated measurements of the depression score, although a number of other covariates were also available, for example, the length of the current episode of depression and whether or not the patient was taking antidepressants. How should such data be analyzed?

Graphical Methods

Graphical displays of data in general, and longitudinal data in particular, are often useful for exposing patterns in the data and this might be of great help in suggesting which more formal methods of analysis might be applicable to the data (*see Graphical Presentation of Longitudinal Data*). According to [3], there is no single prescription for making effective displays of longitudinal data, although they do offer the following simple guidelines:

- they show as much of the relevant raw data as possible rather than only data summaries;
- they highlight aggregate patterns of potential scientific interest;
- they identify both cross-sectional and longitudinal patterns;
- they make easy the identification of unusual individuals or unusual observations.

Two examples of useful graphs for the data from the BtB study are shown in Figures 1 and 2. In the first example, the profiles of individual subjects are plotted, and in the second one, the mean profiles of each treatment group. The diagrams show a decline in depression scores over time, with the BtB group having generally lower scores.

The Analysis of Longitudinal Data

As in other areas, it cannot be overemphasized that statistical analyses of longitudinal data should be no more complex than necessary. So it will not always be essential to use one of the modeling approaches mentioned later since a simpler procedure may often not only be statistically and scientifically adequate but can also be more persuasive and easier to communicate than more ambitious analysis. One simple

Figure 1 Plot of individual patient profiles for data from the BtB study

Figure 2 Plot of treatment profiles for both BtB and TAU groups

(but not simplistic) method for the analysis of longitudinal data is the so-called summary measure analysis process (*see Summary Measure Analysis of Longitudinal Data*). Here, the essential multivariate nature of the longitudinal data is transformed to univariate by the calculation of an appropriate summary of the response profile of each individual. For the BtB data, for example, we might use the mean of the available depression scores for each patient (*see Summary Measure Analysis of Longitudinal Data*).

There may, however, be occasions when there are more complex questions to be asked about

how response measures evolve over time and more problematic data collected than can be adequately handled by the summary measure technique. In such cases, there are a rich variety of regression type models now available that can be usefully employed, the majority of which are implemented in most of the major statistical software packages.

There are a number of desirable general features that methods used to analyze data from studies in which the outcome variable is measured at several time points should aim for – these include the following:

- the specification of the mean response profile needs to be sufficiently flexible to reflect both time trends within each treatment group and any differences in these time trends between treatments;
- repeated measurements of the chosen outcome are likely to be correlated rather than independent. The specification of the pattern of correlations or covariances of the repeated measurements by the chosen model needs to be flexible, but economical;
- the method of analysis should accommodate virtually arbitrary patterns of irregularly spaced time sequences within individuals.

Two very commonly used methods of dealing with longitudinal data, one based on **analysis of variance** (ANOVA), and one on **multivariate analysis of variance** (MANOVA) – (see **Repeated Measures Analysis of Variance** for details) – fail one or other of the criteria above. For an ANOVA repeated measures analysis to be valid, it is necessary both for the variances across time points to be the same, and the covariances between the measurements at each pair of time points to be equal to each other, the so-called compound symmetry requirement (see **Sphericity Test**). Unfortunately, it is unlikely that this compound symmetry structure will apply in general to longitudinal data, since observations from closely aligned time points are likely to be more highly correlated than observation made at time points further apart in time. Also variances often increase over time. The ANOVA approach to the analysis of longitudinal data fails the flexibility requirement of the second bulleted point above.

The MANOVA approach allows for *any* pattern of covariances between the repeated measurements, but

only by including too many parameters; MANOVA falls down on economy.

Fortunately, there are readily available alternatives to ANOVA and MANOVA for the analysis of longitudinal data that are both more satisfactory from a statistical viewpoint and far more flexible. These alternatives are essentially regression models that have two components, the first of which models the average response over time and the effect of covariates such as treatment group on this average response, and the second of which models the pattern of covariances between the repeated measures. Each component involves a set of parameters that have to be estimated from the data. In most applications, it is the parameters reflecting the effects of covariates on the average response that will be of most interest. The parameters defining the covariance structure of the observations will not, in general, be of direct concern (they are often regarded as so-called nuisance parameters). In [2], Diggle suggests that overparameterization (i.e., too many parameters, a problem that affects the MANOVA approach – see above) will lead to inefficient estimation and potentially poor assessment of standard errors for estimates of the mean response profiles; too restrictive a specification (too few parameters to do justice to the actual covariance structure in the data, a problem of the ANOVA method for repeated measures) may also invalidate inferences about the mean response profiles when the assumed covariance structure does not hold.

With a single value of the response variable available for each subject, modeling is restricted to the expected or average value of the response among persons with the same values of the covariates. But with repeated observations on each individual, there are other possibilities. In marginal models, (see **Marginal Models for Clustered Data**), interest focuses on the regression parameters of each response separately (see **Generalized Estimating Equations (GEE)**). But in longitudinal studies, it may also be of interest to consider the *conditional expectation* of each response, given either the values of previous responses or a set of random effects that reflect natural heterogeneity amongst individuals owing to unmeasured factors. The first possibility leads to what are called *transition models* – see [3], and the second to **linear multilevel models**, **nonlinear mixed models**, and **generalized linear mixed models**.

The distinction between marginal models and conditional models for longitudinal data is only

of academic importance for normally distributed responses, but of real importance for repeated nonnormal responses, for example, binary responses, where different assumptions about the source of the correlation can lead to regression coefficients with distinct interpretations (*see* **Generalized Linear Mixed Models**).

Dropouts

The design of most longitudinal studies specifies that all patients are to have the measurement of the outcome variable(s) made at a common set of time points leading to what might be termed a *balanced data set*. However, although balanced longitudinal data is generally the aim, it is rarely achieved in most studies carried out in psychiatry and psychology because of the occurrence of missing values, in the sense that intended measurements on some patients are not taken, are lost, or are otherwise unavailable. In longitudinal studies, missing values may occur intermittently, or they may arise because a participant ‘drops out’ of the study before the end as specified in the study plan. Dropping out of a study implies that once an observation at a particular time point is missing, so are all the remaining planned observations. Many studies will contain missing values of both types, although in practice it is missing values that result from participants dropping out that cause most problems when it comes to analyzing the resulting data set. Missing observations are a nuisance and the very best way to avoid problems with missing values is not to have any! If only a few values are missing, it is unlikely that these will cause any major difficulties for analysis. But in psychiatric studies, the researcher is often faced with the problem of how to

deal with a data set in which a substantial proportion of the intended observations are missing. In such cases, more thought needs to be given to how to best deal with the data. There are three main possibilities:

- discard incomplete cases and analyze the remainder – *complete case analysis*;
- *impute* or fill in the missing values and then analyze the filled-in data;
- analyze the incomplete data by a method that does not require a complete (rectangular) data set.

These possibilities are discussed in **missing data and dropouts in longitudinal studies: methods of analysis**.

Longitudinal Designs in Genetic Research

Longitudinal Experimental Designs

Experiments with a longitudinal design are often called **cohort** or *follow-up* studies. (see **Longitudinal Data Analysis**) They consist of repeated measurements of the same group of experimental subjects (see **Repeated Measures Analysis of Variance**). Longitudinal studies can be contrasted with *cross-sectional* or **case-control** designs, in which multiple measurements are made, but of different groups of subjects. Only longitudinal studies can test changes over time – or changes in response to some treatment or other experimentally controlled variable – in a particular population.

Longitudinal studies come with certain disadvantages. One problem is the age of the subject is confounded with the date of measurement, so that the real effects of age in the measurement sample are confounded with the changes in the whole population over time – so called *secular trends* or *cohort effects*. A second problem is that subjects may drop out of the study before all the measurements have been administered, giving rise to problems of **attrition** (see **Missing Data**).

Longitudinal Correlations and Causality

The correlation between two measurements in a longitudinal sample may be termed a *longitudinal correlation*, and is a measure of how well their relationship conforms to a linear dependency. A correlation between two variables is equivalent to their *covariance* between them, standardized by their *variances*. This encyclopedia entry only considers the kind of change that can be measured by correlations between variables. For information about longitudinal models that consider changes in mean levels as well as correlations between different measurements, see **growth curve models**.

The existence of a longitudinal correlation – or any other correlation – does not imply any particular mode of causality. Correlations can arise by one variable acting causally on the other (Figure 1); or by mutual causality (Figure 2);

Figure 1

Figure 2

Figure 3

or through a shared dependency on a third, causally prior, variable (Figure 3).

When analyzing longitudinal datasets, it is often assumed *a priori* that temporally prior measurements also have causal priority, which ignores the possibility of an underlying shared dependency on a third, unmeasured variable. Whether there are adequate grounds for making this assumption is not a question that can be resolved by the data themselves.

Longitudinal Models as Multivariate Models

Behavioral genetic models typically assume that the variance of an observed variable can be divided up into genetic and environmental *components of variance*. In the case of multivariate behavioral genetic models (see **Multivariate Genetic Analysis**), the relationships among multiple variables are divided up into genetic and environmental pathways that together are responsible for the covariances among the variables. Longitudinal behavioral genetic models are a special case of these multivariate models: the covariances among repeated measurements in a longitudinal design are decomposed in the same

2 Longitudinal Designs in Genetic Research

way. So for example, just as in a standard multivariate behavioral genetic model, the degree of overlap between the genetic influences on two longitudinal measurements can be summarized by the genetic correlation (*see Correlation Issues in Genetics Research*). Likewise, the proportion of the longitudinal correlation between them that is attributable to this shared **heritability** is given by the bivariate heritability (*see Multivariate Genetic Analysis*).

Examples of Longitudinal Behavioral Genetic Models

The Cholesky decomposition. The **Cholesky** (or ‘triangular’) **decomposition** is a *saturated* model, meaning that it has the maximum possible number of parameters that can be estimated from the data. The model assumes that the factors influencing on the phenotype on any given measurement occasion continue to influence the phenotype on all subsequent occasions, and are causally prior to any new influences.

In terms of matrix algebra, if the observed covariance matrix is given by Σ , then the decomposition consists in finding the upper triangular matrix Λ such that

$$\Sigma = \Lambda \Lambda^T \quad (1)$$

In a behavioral genetic model, we can, for example, substitute for Λ the upper triangular matrices of genetic and environmental pathways, A and E , such that

$$\Sigma = AA^T + EE^T \quad (2)$$

Figure 4

This model is represented in Figure 4 for phenotypes measured on three occasions. The uncorrelated latent genetic and environmental variables (A_i and E_j , respectively) act on the observed variables P_t wherever $i, j \leq t$.

The simplex model. The simplex model can be estimated whenever there are three or more measurement occasions. When there are four or more measurement occasions, or when further simplifying assumptions are made, it is an *unsaturated* model – that is, fewer parameters are estimated from the data than is theoretically possible – and therefore imposes a certain structure on the data. Its theoretical starting point is the assumption that the relationships among

Figure 5

phenotypes measured longitudinally can be represented by chains of causal paths, known as *simplex coefficients*, linking the phenotypes on successive measurement occasions. The simplex model requires that the correlations among successive measurements be greater than those between widely spaced measurements. Thus, the correlation matrix between phenotypes conforming to a simplex structure contains coefficients that are greatest between successive measurements (those adjacent to the leading diagonal) and fall off as the measurements become spaced further apart (i.e., as the distance to the leading diagonal increases).

Figure 5 represents a behavioral genetic example for a phenotype P measured on four occasions. The simplex coefficients are represented by horizontal paths, modeling the continuity between successive

latent genetic (A) and environmental (E) variables. The slanted paths on the diagram represent new genetic and environmental variance on the phenotype, uncorrelated with previous measurements – the *innovations*. Note that the continuity between widely spaced latent variables (A₁ and A₄, say) is mediated by the latent variables on intermediate measurement occasions (in this case, A₂ and A₃).

In terms of matrix algebra, the covariance matrix Σ is a function of diagonal matrices of genetic and environmental innovations (I_A and I_E , respectively) and sub lower matrices of simplex coefficients (S_A and S_E):

$$\Sigma = I_A S_A I_A^T + I_E S_E I_E^T \quad (3)$$

Lord, Frederic Mather

Born: November 12, 1912, in Hanover, USA.

Died: February 5, 2000, in Florida, USA.

Dr. Frederic Lord was described as the ‘Father of Modern Testing’ by the National Council on Measurement in Education in the United States when he received their career achievement award in 1991. The Educational Testing Service in the United States bestowed upon Dr. Lord their highest honor for ‘... the tremendous achievements and contributions, not just to the Educational Testing Service (ETS) but nationally and internationally, as the principal developer of the statistical underpinnings supporting modern mental testing, providing the theoretical structure for **item response theory** (IRT), which allowed for effective test equating and made possible modern computer-adaptive tests...’ The American Psychological Association in 1997 selected Dr. Lord to receive one of its achievement awards for a lifetime of seminal and important contributions to the field of test theory. And these are just three of many of the awards Dr. Lord receiving during his life. It is clear that Dr. Lord’s contributions to psychometric theory and practices place him among the most influential and productive psychometricians of the twentieth century.

Dr. Lord was born in Hanover, New Hampshire, in 1912, earning a BA degree in Sociology from Dartmouth College in 1936; a masters degree in Educational Psychology from the University of Minnesota in 1943; and finally achieving a PhD from Princeton in 1951 under the direction of Harold Gulliksen, another of the outstanding contributors to psychometric theory and practices in the twentieth century. Beginning in 1944, Dr. Lord gained some early experience in psychometric methods by working with the predecessor of the Educational Testing Service (ETS), the Graduate Record Office of the Carnegie Foundation, and he joined ETS when it was officially founded in 1949. Dr. Lord spent his whole career at ETS, except for sabbaticals that took him to several universities in the United States. He retired from ETS in 1982.

Dr. Lord will be forever influential in the field of psychometric methods because of three seminal publications and over 100 scholarly journal articles and

chapters. In 1952, his dissertation research introducing modern test theory, today called ‘Item Response Theory’, was published as *Psychometric Monograph No. 7* [2]. This publication was the first formal one that provided mathematical models for linking candidate responses on achievement test items to underlying constructs or abilities that were measured by a test. He followed up his monograph with papers in the 1953 editions of *Psychometrika* and *Educational and Psychological Measurement* that showed how IRT was linked to true score theory, and how **maximum likelihood** ability estimates could be obtained and confidence bands (*see Confidence Intervals*) about these ability estimates determined. But then Lord stopped this line of research for about 15 years, presumably because the computer power was not available to solve the complicated and numerous nonlinear equations needed for IRT model parameter estimation. Clearly, the research published by Lord in 1952 and 1953 did not satisfy him. He was forced to assume that ability scores were normally distributed, and that, for all practical purposes, guessing on multiple-choice achievement test items did not occur. These unrealistic assumptions allowed him to simplify the maximum likelihood equations and to solve them in 1952, but he was not happy with the assumptions he needed to make, and he was reluctant to move forward in his research with these flawed assumptions. He would need to wait for more computer power before moving forward with his IRT program of research.

For the next 15 years or so, Dr. Lord studied many psychometric problems such as those associated with equating, norming, measurement of change, formula scoring, and most importantly, true score theory. It was in this era that he built his reputation for scholarship and creative problem solving. His impact on ETS was huge, with many of their standard operating procedures, such as test score equating (*see Classical Test Score Equating*), being based on his research and suggestions. ETS then, and today, remains the mecca for testing theory and practices, and so his work at the time had an immense impact on the ways testing was carried out around the world.

In 1968, Dr. Lord, with the great assistance of Melvin Novick and Alan Birnbaum, produced his second seminal publication *Statistical theories of mental test scores*, which has had an immense impact on the testing field for over 30 years [4]. This book extended the work of Gulliksen’s *Theory of Mental*

Tests [1] by providing a statistical framework for developing tests and analyzing test scores. It was the culmination for Dr. Lord's efforts between 1952 and 1967 to extend the models and results of **classical test theory**. This book became required reading for a generation of psychometricians. I carried my copy of 'Lord and Novick', as we called it, just about everywhere I went for the first 10 years of my career!

The Lord–Novick text remains the standard reference for persons interested in learning about classical test theory. But the book will be long remembered for something else too – it was the first text that provided extended coverage of IRT: five chapters in total. With huge improvements in the speed with which computers could solve large numbers of nonlinear equations and with his keen interest in computer-adaptive testing, a topic that required IRT as a measurement model, Dr. Lord became committed again to advancing IRT. In the late 1960s, model parameter estimation became possible without a highly restrictive normal distribution assumption of ability. Also, Lord's colleague Allan Birnbaum in the late 1950s wrote a series of reports in which he substituted the logistic model for the normal ogive model as the basis for modeling data and introduced an additional parameter into his logistic models to handle the guessing problem that had worried Lord in the early 1950s. Lord contributed Chapter 16 to *Statistical Theories of Mental Test Scores*, and Birnbaum provided Chapters 17 to 20 [4]. Because of the influence of Lord and Novick's book along with the work of Georg Rasch, item response theory took off as an area for research and development.

Through the 1970s, Lord made breakthrough contributions to IRT topics such as equating, estimation of ability, the detection of potentially biased items, test development, and his favorite IRT application, **computer-adaptive testing**. All of this and more was included in his third seminal publication, *Applications of Item Response Theory to Practical Testing Problems* [3]. No book has been more important than this one in advancing the IRT field. Lord retired in 1982 but continued his research at ETS until his career was cut short by a serious car accident in South Africa in 1985. Dr. Lord spent the remaining years of his life in retirement with his wife, Muriel Bessemer, in Florida.

I will conclude with one brief personal story. In 1977, I invited Dr. Lord to speak at the annual meeting of the American Educational Research Association as a discussant of a monograph prepared by

a colleague and myself and three graduate students from the University of Massachusetts. I sent him the 130-page monograph, and soon after I received it back with editorial comments. This was unexpected. First, Dr. Lord felt we had been far too generous in our recognition of his contributions to the field of IRT and he wanted us to revise the monograph to more accurately reflect the work of his colleagues. We disagreed but revised the text to reflect Lord's wishes. Second, he felt that we had made some minor errors, and he preferred that our monograph be revised before any distribution. I think his comment was that 'the field would be less confused if there were fewer misunderstandings and so it would be in the best interests of everyone if the monograph were revised'. He wanted no recognition for his input to our work, he only wanted to be sure that the monograph be correct in every respect when it was read by researchers and students. When he delivered his remarks at the conference, he read them from a carefully prepared speech, not the usual kind of presentation given by a discussant working from rough notes, some jotted down during the presentations. All of the speakers and the conference attendees, and the conference room itself jammed with people wanting to hear Dr. Lord, hung on every word he had to say. He prepared his text in advance because he wanted to be sure that what he said was exactly what he wanted to say, no more, no less, and he wanted to deliver his message with great care and technical precision. What came through that day for me was that Dr. Lord was a man who cared about getting things right, exactly right, and he spoke clearly, thoughtfully, and with great precision about how to move the testing field forward. He was a superb example for all of us working in the assessment field.

Lord's Paradox

Following Lord in [3], suppose a researcher wishes to compare two groups on some criterion variable, Y , and would like to make allowance for the fact that the groups being compared differ on some important independent variable X . The situation is such that the observed differences in Y might be caused by the differences in X , and the researcher wishes to rule out this possibility.

With measurements on Y and X made for each person in each of two groups, the thought of using the **analysis of covariance** is irresistible to some. Lord's intended purpose was to warn them that the interpretation of the results of such analyses could be problematic.

He illustrated his points with a simple example. Taking small liberties with Lord's language, suppose a university wants to investigate the effects of the diet provided in the dining halls and any differences in these effects between men and women. To this end, they collect the weight of each student at registration in the fall and again later at the end of the spring term. Two of the university's distinguished statisticians, Henry and Howard, offer to analyze the results, and they use different methods.

Henry studies the distribution of weight for each gender group and finds that while men on average weigh more than women, the average weight of each group is unchanged from fall and spring. The correlation between the fall and spring weights is both positive and substantial in each gender group. But, while the weights of individual students often change between the two time points, some go up and some go down. A sort of dynamic equilibrium appears to be maintained over the year within each gender group. Henry concludes that with respect to the distribution of weight nothing systematic has occurred, either for men or for women.

Howard sees this as a natural place to apply the analysis of covariance and uses **multiple regression** to do the calculations. There are two groups, men and women, and two measurements for each, with Y being the spring weight and X being the fall weight. He estimates a regression function that predicts Y from both X and an indicator variable M , that is 1 for males and 0 for females. (He also checks that if he adds the interaction or product term, $X \times M$,

as a predictor it has no extra contribution so that the regressions of Y on X are parallel for the two groups.) There is a significant and substantial positive coefficient on M . This coefficient is the regression-adjusted (for X) difference in spring weights between men and women. Howard correctly interprets this as the average amount more that a male will weigh in the spring, compared to a female whose fall weight is the same. Whatever the diet is doing to their weight, it is adding more weight to men than it does to equally weighing women! In [3], Lord gives a diagram showing that the results found by Henry and Howard are compatible.

The paradox is that while Henry seems reasonable in his conclusion that the diet did not have any systematic effect between the fall and the spring, either for men or women, Howard observes that indeed men will gain more on the diet than will equally weighing women.

Lord's explanation of the paradox is that 'with the data usually available in such studies, there simply is no logical or statistical procedure that can be counted on to make proper allowances for uncontrolled preexisting differences between groups'. In program evaluation, it is common to use nonrandomized observational studies in which treatment and control groups do exhibit 'uncontrolled preexisting differences', and therefore Lord's paradox quickly became part of the lore surrounding program evaluation, [4].

As it stands, there are several points of ambiguity in the language that is used to describe Lord's paradox. What is meant by 'making allowance for...'? What meaning should we attach to the idea that differences in X could cause differences in Y ? What exactly is the researcher trying to rule out? What are 'pre-existing group differences'? Will any treatment group do? Holland and Rubin give an extended explanation of Lord's paradox in [2], and my treatment is based on theirs but I will focus only on the example described above.

Asking about the effect of a treatment, in this case, the effect of the diet, is a causal question, and the causal effect of a treatment is always defined relative to another treatment, [1]. But, this example has only one treatment condition, that is, the diet that is used in the dining halls. There is no control diet here, yet if we would like to talk about the *effect* of the diet it must be relative to some other, control, diet. In the notation of the Neyman-Rubin model

[1], in order to make causal sense of the situation, there need to be two potential spring weights, Y_t and Y_c for each student. Y_t is the student's spring weight that results from the dining hall diet (t) and Y_c is the student's spring weight that would have resulted from the control diet (c), whatever that might be. In this example, only Y_t is observed. For each student, Y_c is **counterfactual reasoning** and we are left to speculate as to what Y_c is. It turns out that if they make causal inferences about the effect of the diet, Henry and Howard must have different Y_c 's in mind.

The causal effect of t relative to c on the spring weight of a student is the difference, $Y_t - Y_c$. The *average causal effect* (ACE) is the average or expectation of these individual causal effects over the population of students: $ACE = E(Y_t - Y_c) = E(Y_t) - E(Y_c)$. In this example, there is also an interest in differences in effects between men and women. Using the indicator variable, M , defined above, this means that not only are we interested in the ACE, we also want the values of the 'conditional' ACEs of the form: $ACE(\text{men}) = E(Y_t - Y_c | M = 1)$, and $ACE(\text{women}) = E(Y_t - Y_c | M = 0)$. If the effect of the diet is different for men and women, this will be reflected by differences between the average causal effects for men and for women.

With no clear control diet in hand, it is a daunting task to obtain values for either the ACE or for $ACE(\text{men})$ and $ACE(\text{women})$. However, most examples of causal inference must make some assumptions that are often not directly testable, and we may interpret causal interpretations of Henry's and Howard's analyses as based on different assumptions.

Henry assumes that $Y_c = X$, that is, the response to the control diet is the same as the student's fall weight. For Henry, the causal effect for any student is the gain score, $Y_t - X$. This is an entirely untestable assumption, but look where it gets Henry!

$$ACE_{\text{Henry}} = E(Y_t - Y_c) = E(Y_t) - E(X). \quad (1)$$

and

$$\begin{aligned} ACE_{\text{Henry}}(\text{men}) &= E(Y_t | M = 1) \\ &\quad - E(X | M = 1) = 0, \end{aligned} \quad (2)$$

$$\begin{aligned} ACE_{\text{Henry}}(\text{women}) &= E(Y_t | M = 0) \\ &\quad - E(X | M = 0) = 0. \end{aligned} \quad (3)$$

From his assumption, the effect of the diet is nil, both for men and for women.

Howard, on the other hand, assumes that $Y_c = a + bX$, where b is the slope on X from his estimated regression function. Again, this is an entirely untestable assumption, but look where it gets Howard!

$$\begin{aligned} ACE_{\text{Howard}} &= E(Y_t) - E(a + bX) \\ &= E(Y_t) - a - bE(X). \end{aligned} \quad (4)$$

and

$$\begin{aligned} ACE_{\text{Howard}}(\text{men}) &= E(Y_t | M = 1) \\ &\quad - a - bE(X | M = 1) \end{aligned} \quad (5)$$

$$\begin{aligned} ACE_{\text{Howard}}(\text{women}) &= E(Y_t | M = 0) \\ &\quad - a - bE(X | M = 0) \end{aligned} \quad (6)$$

so that the difference between the gender specific ACEs is

$$\begin{aligned} ACE_{\text{Howard}}(\text{men}) - ACE_{\text{Howard}}(\text{women}) &= E(Y_t | M = 1) - E(Y_t | M = 0) \\ &\quad - b[E(X | M = 1) - E(X | M = 0)]. \end{aligned} \quad (7)$$

The last expression is the mean difference between male and female spring weights that is regression-adjusted by their fall weight. This is the parameter estimated by the analysis of covariance.

Who is right? In an example like this, where the control condition is fictitious, it is hard to say. Perhaps some will favor Henry's assumption while others may prefer Howard's or some other assumption. It is certain that there is nothing in the data at hand to contradict either or any assumption about Y_c .

Another approach to resolving the paradox is simply to avoid making the causal inferences. This lowers our sights to descriptions of the data rather than attempting to draw causal inferences from them. From this point of view, there is just Y and X , no t or c , and both Henry's description of an apparent 'dynamic equilibrium' and Howard's description of spring weights for men and women conditional on fall weight are both equally valid. Both statisticians are 'right' but they are talking about very different things, and neither has any relevance to the *effects* of the dining hall diet.

M Estimators of Location

Under normality, the sample mean has a lower standard error than the mean and median. A consequence is that hypothesis testing methods based on the mean have more **power**; the probability of rejecting the null hypothesis is higher versus using the median. But under nonnormality, there are general conditions under which this is no longer true, a result first derived by **LaPlace** over two centuries ago. In fact, any method based on means can have poor power.

This raises the issue of whether an alternative to the mean and median can be found that maintains relatively high power under normality but continues to have high power in situations in which the mean performs poorly. Three types of estimators aimed at achieving this goal have received considerable attention: M-estimators, L-estimators, and R-estimators. L-estimators contain trimmed and Winsorized means, and the median, as special cases (*see Trimmed Means; Winsorized Robust Measures*).

To describe M-estimators, first consider the **least squares** approach to estimation. Given some data, how might we choose a value, say c , that is typical of what we observe? The least squares approach is to choose c so as to minimize the sum of the squared differences between the observations and c . In symbols, if we observe $X_1, \dots, X_n$, the goal is to choose c so as to minimize

$$\sum (X_i - c)^2.$$

This is accomplished by setting $c = \bar{X}$, the sample mean. If we replace squared differences with absolute values, we get the median instead. That is, if the goal is to choose c so as to minimize

$$\sum |X_i - c|,$$

the answer is the usual sample median. But the sample mean can have a relatively large standard error under small departures from normality [1, 3–6], and the median performs rather poorly if sampling is indeed from a normal distribution. So an issue of some practical importance is whether some measure of the difference between c and the observations can be found that not only performs relatively well under normality but also continues to perform well in situations where the mean is unsatisfactory.

Several possibilities have been proposed; see, for example, [2–4]. One that seems to be particularly useful was derived by Huber [2]. There is no explicit equation for computing his estimator, but there are two practical ways of dealing with this problem. The first is to use an iterative estimation method. Software for implementing the method is easily written and is available, for example, in [6]. The second is to use an approximation of this estimator that inherits its positive features and is easier to compute. This approximation is called a one-step M-estimator.

In essence, a one-step M-estimator searches for any **outliers**, which are values that are unusually large or small. This is done using a method based on the median of the data plus a measure of dispersion called the **Median Absolute Deviation** (MAD). (Outlier detection methods based on the mean and usual standard deviation are known to be unsatisfactory; see [5] and [6].) Then, any outliers are discarded and the remaining values are averaged. If no outliers are found, the one-step M-estimator becomes the mean. However, if the number of outliers having an unusually large value differs from the number of outliers having an unusually small value, an additional adjustment is made in order to achieve an appropriate approximation of the M-estimator of location. There are some advantages in ignoring this additional adjustment, but there are negative consequences as well [6].

To describe the computational details, consider any n observations, say $X_1, \dots, X_n$. Let M be the median and compute

$$|X_1 - M|, \dots, |X_n - M|.$$

The median of these n differences is MAD, the **Median Absolute Deviation**. Let $\text{MADN} = \text{MAD}/0.6745$, let i_1 be the number of observations X_i for which $(X_i - M)/\text{MADN} < -K$, and let i_2 be the number of observations such that $(X_i - M)/\text{MADN} > K$, where typically $K = 1.28$ is used to get a relatively small standard error under normality. The one-step M-estimator of location (based on Huber's Ψ) is

$$\hat{\mu}_{\text{os}} = \frac{K(\text{MADN})(i_2 - i_1) + \sum_{i=i_1+1}^{n-i_2} X_{(i)}}{n - i_1 - i_2}. \quad (1)$$

2 M Estimators of Location

Computing a one-step M-estimator (with $K = 1.28$) is illustrated with the following ($n = 19$) observations:

77 87 88 114 151 210 219 246 253 262 296 299
306 376 428 515 666 1310 2611.

It can be seen that $M = 262$ and that $MADN = MAD/0.6745 = 114/0.6745 = 169$. If for each observed value we subtract the median and divide by MADN, we get

-1.09 -1.04 -1.035 -0.88 -0.66 -0.31
-0.25 -0.095 -0.05 0.00 0.20 0.22 0.26
0.67 0.98 1.50 2.39 6.2 13.90

So there are four values larger than the median that are declared outliers: 515, 666, 1310, 2611. That is, $i_2 = 4$. No values less than the median are declared outliers, so $i_1 = 0$. The sum of the values not declared outliers is

$$77 + 87 + \cdots + 428 = 3411.$$

So the value of the one-step M-estimator is

$$\frac{1.28(169)(4 - 0) + 3411}{19 - 0 - 4} = 285.$$

Mahalanobis Distance

It may be recalled from studying the Pythagorean theorem in a geometry course that the (Euclidean) distance between two points, (x_1, y_1) and (x_2, y_2) (in a two-dimensional space), is given by

$$d = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2}. \quad (1)$$

From a statistical viewpoint, the two variables involved are uncorrelated; also, each variable has a standard deviation of 1.0. It was in 1936 that a statistician from India, **Prasanta C. Mahalanobis**, (1893–1972) introduced a generalization of the distance concept while investigating anthropometric problems [1]. It is a generalization in the sense of dealing with more than two variables whose inter-correlations may range from -1.0 to 1.0 , and whose standard deviations may vary.

Let there be a set of p variables. For a single analysis unit (or, subject), let $\mathbf{x}_i$ denote a vector of p variable scores for unit i . Also, let $\mathbf{S}$ denote the $p \times p$ **covariance matrix** that reflects the p variable interrelationships. Then, the Mahalanobis distance between unit i and unit j is given by

$$D_{ij} = \sqrt{(\mathbf{x}_i - \mathbf{x}_j)' \mathbf{S}^{-1} (\mathbf{x}_i - \mathbf{x}_j)} \quad (2)$$

where the prime denotes a matrix transpose and $\mathbf{S}^{-1}$ denotes the inverse of $\mathbf{S}$ – the inverse standardizes the distance. (The radicand is a $(1 \times p)(p \times p)(p \times 1)$ triple product that results in a scalar.) Geometrically, $\mathbf{x}_i$ and $\mathbf{x}_j$ represent points for the two units in a p -dimensional space and D_{ij} represents the distance between the two points (in the p -dimensional space).

Now, suppose there are two groups of units. Let $\bar{\mathbf{x}}_1$ represent the vector of p means in group 1; similarly for group 2, $\bar{\mathbf{x}}_2$. Then, the distance between the two

mean vectors (called *centroids*) is analogously given by the scalar

$$D_{12} = \sqrt{(\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2)' \mathbf{S}^{-1} (\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2)}. \quad (3)$$

This D_{12} represents the distance between the two group centroids. The $\mathbf{S}$ matrix used is generally the two-group error (or, pooled) covariance matrix.

A third type of Mahalanobis distance is that between a point representing an individual unit and a point representing a group centroid. The distance between unit i and the group 1 centroid is given by

$$D_{i1} = \sqrt{(\mathbf{x}_i - \bar{\mathbf{x}}_1)' \mathbf{S}^{-1} (\mathbf{x}_i - \bar{\mathbf{x}}_1)}. \quad (4)$$

The $\mathbf{S}$ matrix here may be the covariance matrix for group 1 or, in the case of multiple groups, the error covariance matrix based on all of the groups.

In sum, there are three types of Mahalanobis distance indices:

- D_{ij} – unit-to-unit,
- D_{12} – group-to-group, and
- D_{i1} – unit-to-group.

These distance indices are utilized in a little variety of multivariate analyses. A summary of some uses is provided in Table 1.

As alluded to earlier, a Mahalanobis D value may be viewed as a standardized distance. Jacob Cohen (1923–1998) in 1969 [2]. The *Cohen d*, is applied in a two-group, one outcome-variable context. Let x denote the outcome variable, s denote the standard deviation of one group of x scores (or the error standard deviation for the two groups), and $\bar{x}_1$ denote the mean of the outcome variable scores for group 1. The Cohen index, then, is

$$d_{12} = \frac{\bar{x}_1 - \bar{x}_2}{s} = (\bar{x}_1 - \bar{x}_2)s^{-1} \quad (5)$$

Table 1 The use of distance indices in some multivariate analyses

	Unit-to-unit	Group-to-group	Unit-to-group

Predictive discriminant analysis		X	X
Cluster analysis	X		X
Pattern recognition			X
Multivariate outlier detection			X

2 Mahalanobis Distance

which is a special case of D_{12} . This d_{12} is sometimes considered as an *effect size* index (see **Effect Size Measures**).

Mahalanobis, Prasanta Chandra

Born: June 29, 1893, in Calcutta, [1].

Died: June 28, 1972, in Calcutta, [1].

Mahalanobis once invoked a mental construct of ‘five concentric circles’ to characterize the domains of science and statistics [3]. At the center is physics and at the outer layers are survey methods or areas where the variables are mostly unidentifiable, uncontrollable and ‘free’. As a student of physics and mathematics at Cambridge [4], he began his own career at the central geometric point of this construct. By the end of his life, he had made theoretical and applied contributions to every sphere. In 1922, he became professor of Physics at the Presidency College in Calcutta [7]. As ‘a physicist by training, statistician by instinct and a planner by conviction’ [9], his interests led him to found the Indian Statistical Institute (ISI) in 1931 [10] to promote interdisciplinary research. In 1933, he launched the internationally renowned journal *Sankyā*, serving as editor for forty years. Among Mahalanobis’ various achievements at the ISI were the establishment of undergraduate, postgraduate and Ph.D. level courses in statistics, and the reform in 1944 to make the ISI fully coeducational [5, 10]. His work made Delhi the ‘Mecca’ of statisticians, economists and planners world-wide [9]. At the national level, the Professor was chair of the National Income Committee set up by the Government of India in 1949 [1]. Mahalanobis was involved in the establishment of the Central Statistical Organization, the Perspective Planning Division in the Planning Commission and the National Sample Survey (perhaps his biggest achievement) [2]. In 1954, Prime Minister Nehru enlisted Mahalanobis to plan studies at the ISI to inform India’s second and third Five Year Plans [10] and he became honorary Statistical Adviser to the Government [4]. To economists, this was an important contribution [3, 7] and it is noteworthy that his lack of training in economics did not prevent him from undertaking this major responsibility [10]. He disliked accepted forms of knowledge and enjoyed problems that offered sufficient subject challenge, regardless of the topic [7]. When dealing with economic problems, he was used to saying that

he was glad he was not exposed to formal education in economics [8]! He developed the *Mahalanobis Model*, which was initially rejected by the planning commission. However, Nehru approved the model and their combined efforts have been described as ‘the golden age of planning’ [3]. The ISI was declared an Institute of national importance by the Parliament in 1959 with guaranteed funding. It had previously survived on project and *ad hoc* grants. The Indian Statistical Service (ISS) was established in 1961 [10] and the Professor was elected Fellow of the Royal Society of Great Britain in 1945 for his outstanding contributions to theoretical and applied statistics [9]. Other international awards included Honorary Member of the Academy of Sciences in the USSR and Honorary Member of the American Academy of Sciences. He was frequently called upon to collaborate with scientific research and foreign scientists [2, 4]. The ISI itself worked with scientists from the USSR, UK, USA and Australia.

The Professor’s contributions to the theory and practice of large-scale surveys have been the most celebrated [7]. His orientation in physics served as a starting point [8]. The three main contributions were [7]: (a) to provide means of obtaining an optimal sample design, which would either minimize the sampling variance of the estimate for a given cost, or minimize the cost for a given standard error of the estimate; (b) to show how one or more pilot surveys could be utilized to estimate the parameters of the variance and cost functions; (c) to suggest and use various techniques for measurement and control of sampling and nonsampling errors. He developed ‘interpenetrating network of samples in sample surveys’, which can help control for observational errors and judge the validity of survey results. The technique can also be used to measure variation across investigators, between different methods of data collection and input, and variation across seasons [7]. Total variation is split into three components: sampling error, ascertainment error, and tabulation error. In modern terminology, Mahalanobis’ four types of sampling (unitary unrestricted, unitary configurational, zonal unrestricted, and zonal configuration) correspond to unrestricted simple random sampling, unrestricted cluster sampling, stratified simple random sampling, and stratified cluster sampling [8] (*see Survey Sampling Procedures*). His watchwords were randomization, statistical control, and cost [8]. However, he also believed that samples should be independently

investigated and analyzed, or at the very least be split into two subsamples for analysis, despite the increase in cost.

The statistic **Mahalanobis distance** is perhaps the most widely known aspect of Mahalanobis' work today. This statistic is used in problems of taxonomical classification [10], in cluster analysis (*see Cluster Analysis: Overview; Hierarchical Clustering*) and for detecting multivariate **outliers** in datasets. It is helpful when drawing inferences on interrelationships between populations and speculating on their origin, or for measuring divergence between two or more groups. Alternative measures of quantitative characteristics such as social class can be compared using it [5]. **Pearson** rejected a paper on this area of work for the journal *Biometrika*, but **Fisher** soon recognized the importance of the work and provided the term *Mahalanobis D^2* . In later life, Mahalanobis developed *Fractile Graphical Analysis* (FGA), a nonparametric method for the comparison of two samples. For example, it can be used to compare the characteristics of a group at different time-points, or two groups at different places. It can also be used to test the normality or log normality or a frequency distribution [6]. The Professor also developed educational tests, studies of the correlations between intelligence or aptitude tests and success in school leaving certificates and other examinations. He made important contributions to factor analysis, which appear in early volumes of *Sankya*. His work on soil heterogeneity led him to meet Fisher and they became friends. They shared views on the foundations and the methodological aspects of statistics, and also on the role of statistics as a new technology.

Perhaps unusually, Mahalanobis had numerous interests outside his scientific pursuits. He was interested in art, poetry (particularly of Rabindranath Tagore) and literature [7], anthropology [11], and architecture. The various social, cultural, and intellectual movements in Bengal were also sources of interest. He was not 'an ivory-tower scholar or arm-chair intellectual', and 'hardly any issue of the time failed to make him take a stand one way or the other' [7]. Economic development was one of many broader objectives he believed in: including social change, modernization, national security and international peace [11]. Because he was on such good terms with Indian and world politicians [10], it has been said that Mahalanobis was the only scientist in the world who, when the Cold War was at its height,

was received with as much warmth in Washington and London as in Moscow and Beijing.

A genius for locating talent, Mahalanobis' approach to recruitment prevented a 'brain drain' from the ISI. He employed a strategy called 'brain irrigation', paying low salaries for posts earmarked for individual people [11]. When they left, the post disappeared. He felt that job security bred inefficiency and used this technique as a screening, quality control mechanism. His personality was unmistakably conscientious and driven, but a flair for argument and an impatience for bureaucracy 'made the Professor a fighter all his life' [3]. He believed in the public sector but not the typical civil servant [11] who he saw as inefficient, with little idea of the function and use of science. He struggled with governmental bureaucrats continuously in order to retain the autonomy of the ISI. He could talk with great effectiveness in small groups, using his histrionic talents to command attention, but was less effective in larger gatherings [6]. His character has been summarized as tough, courageous, tenacious, bold [6], intellectual, dynamic, devoted, loving, proud [3], odd (particularly in his attitude to money), but periodically despondent and depressed [11]. Four principal qualities outlined by Chatterjee [3] were: (a) practical mindedness: a preference for things tangible rather than abstract; (b) breadth of vision and farsightedness, a knack for looking beyond problems to envisage the long-term implications of possible solutions; (c) extraordinary organizing ability, although his wife Rani helped alleviate occasional absent mindedness [11]; (d) an innate sense of humanism and nationalism: strengthened in later life by his contacts with Nehru and Tagore [7]. The resourcefulness of his personality and the variety of his works set Mahalanobis apart from other scientists of his time [5].

Many types of research were welcomed at the ISI, but Rudra [11] recalled the Professor saying, 'There is one kind of research that I shall not allow to be carried out at the Institute. I will not support anybody working on problems of aeronavigation in viscous fluid'. He therefore did not approve of research that neither had any contribution to pure theory nor to solving practical problems. Knowledge was for socially useful purposes, and this conviction found expression in the later phases of his life [7]. Mahalanobis paid almost equal attention to both theoretical and applied statistical research.

According to him, statistics was an applied science: its justification centered on the help it can give in solving a problem [7].

Mail Surveys

A mailed survey is one of several methods of collecting data that researchers can use to answer questions from a sample of the population. Mailed surveys usually involve the research team mailing a questionnaire to a potential respondent who then fills it out and returns the survey by mail. The major advantage of the mailed survey approach is its relatively low cost for data collection compared to telephone surveys or in-person interview surveys. A disadvantage of mailed surveys is that they often achieve a much lower response rate – percent of persons returning the survey from all of those asked to fill out the survey – than other data collection methods. Research studies conducted over the past few decades, however, have found ways to improve response rates to mailed surveys in many situations [5, 17–19, 44].

One general way to improve response rates to mailed surveys is to use this methodology only when it is appropriate. Mailed surveys are a good data collection choice when:

1. the budget for the study is relatively modest;
2. the sample of respondents are widely distributed geographically;
3. the data collection for a large sample needs to be completed in a relatively short time frame;
4. the validity of the answers to the questions would be improved if respondents could answer questions at their own pace;
5. the extra privacy of not having to give the answers to an interviewer would improve the veracity of the answers;
6. the study has a modest number of questions; and
7. the research sample has a moderate to high interest in the survey topic.

All mailed survey studies should incorporate three basic elements. The study mailing should include a well-crafted respondent letter, a preaddressed and postage-paid return envelope, and include a promise of confidentiality of answers or, preferably, anonymity of answers.

How the respondent letter is written is important because it is usually the sole mechanism for describing the study's purpose, explaining the procedures to be followed, and motivating the respondent to participate [2, 12, 43, 46, 74]. The following features

contribute to a well-crafted letter: it is not too long (limit to one page if possible); it begins with an engaging sentence; it clearly tells the respondent why the study is important; it explains who the sample is and how people were selected; it explains how confidentiality will be maintained; it indicates that participation is voluntary but emphasizes the importance of participation; it is printed on letterhead that clearly identifies the research institution; it tells the respondent how to return the survey; and it is easy to read in terms of type size, layout, and language level.

Early studies of mail surveys showed that including a preaddressed and postage-paid envelope is critically important to the success of a mail survey [3, 6, 38, 61, 67, 81]. Interestingly, research also has shown that using pretty commemorative stamps on both the initial delivered package and the return envelope improve response rates slightly [41, 50, 59].

Confidentiality is provided by not putting names on the surveys but instead using an ID number. Furthermore, confidentiality is maintained by keeping returned surveys under lock and key, keeping the list which links ID numbers to names in a separate locked place or password protected file, and presenting the data in reports in such a way that individuals are not identified. Anonymity can be achieved by not putting an ID number or other identifier on the surveys so that when they are returned the researcher does not know who returned it. Using this procedure, however, makes it difficult to send reminders to those who did not return their survey [7, 8, 14, 15, 25, 31, 34, 35, 54, 62, 66, 69, 78].

Beyond these three basic elements, there are two major strategies for improving response rates – sending reminders to those who have not responded and providing incentives to return the survey. The goal of a reminder is to increase motivation to respond. Reminders are best sent just to those who have not returned the survey so that the language of the reminder letter can be focused on those who have not returned their survey. Reminders should be sent out approximately 10 to 14 days after the previous mailing. This interval is not too short and hence will not waste a reminder on someone who intends to return the survey. Also, the interval is not too long, so that nonparticipating respondents will still remember what this is about. The first reminder should just be a postcard or letter and encourage the respondent to complete their survey. The second reminder should include answers to probable concerns the respondents

2 Mail Surveys

might have in not returning the survey as well as a replacement copy of the survey itself. The third reminder should again be a letter or postcard and the content should focus on the message that this is the last chance to participate. Some studies alter the last reminder by using a telephone reminder or delivering the letter with some type of premium postage like special delivery or overnight mail [16, 20, 23, 24, 26, 28, 33, 46, 49, 51, 53, 56, 81].

There is one important variation on these methods if you want to both provide anonymity to respondents and be able to send reminders to those who have not responded. The surveys are sent without any sort of ID number on them. However, in addition, the initial mailed packet includes a postcard. The person's name or ID number are printed on the postcard. On the back of the postcard is a message from the respondent to the study director. It says, 'I am returning my survey, so I do not need any more reminders'. The respondents are instructed in the respondent letter and maybe also at the end of the survey, to return the survey *and* the postcard, *but* to return them separately in order to maintain anonymity. By using this dual return mechanism, study directors can send reminders only to those who have not returned their surveys while at the same time maintaining anonymity of the returned surveys. The major concern in using this procedure is that many people will return the postcard but *not* the surveys. This turns out not to be the case. In general, about 90% of those returning their surveys also return a postcard. Almost certainly there are some people among the 90% who do not return their surveys, but the proportion is relatively small.

Incentives are the other strategy to use to improve response rates. Lots of different incentive materials have been used such as movie tickets, ball-point pens, coffee mugs, and cash or checks. The advantage of money or checks is that the value of the incentive is clear. On the other hand, other types of incentives may be perceived of having value greater than what was actually spent [22, 29, 32, 40, 42, 51, 56, 73, 81, 82].

There are three types of incentives based on who gets them and when. The three types are 'promised-rewards', 'lottery awards', and 'up-front rewards'. Promised rewards set up a 'contract' with the potential respondent such as: 'each person who sends back the completed survey will be paid \$5'. Although improvements in response rates compared to no incentive studies have been observed for

this approach, the improvements are generally modest [82].

Lottery methods are a form of promised-reward, but with a contingency – only one, or a few, of the participating respondents will be randomly selected to receive a reward. This method also differs from the promised rewards method in that the respondents who are selected receive a relatively large reward – \$100 to \$1000 or sometimes more. Generally speaking, the effectiveness of the lottery method over the basic promised-reward strategy depends on the respondents' perceptions of the chances of winning and the attractiveness of the 'prize' [36, 42, 58].

Up-front incentives work the best. For this method, everyone who is asked to participate in a study is given a 'small' incentive that is enclosed with the initial mailing. The incentive is usually described as a 'token of our appreciation for your participation'. Everyone can keep the incentive whether or not they respond. This unconditional reward seems to establish a sense of trust and admiration for the institution carrying out the study and thereby motivates respondents to 'help out these good people' by returning their survey. The size of the up-front incentive does not have to be that large to produce a notable increase in response rates. It is common to see incentives in the \$5–\$10 range [6, 37, 72, 79].

To get the best response rates, it is recommended that researchers use both reminders and incentives in their study designs [47]. When applying both procedures, it is not unusual to achieve response rates in the 60 to 80% range. By comparison, studies that only send out a single mailing with no incentives achieve response rates of 30% or less.

In addition to these two major procedures to improve response rates, there are a variety of other things that can be done by the researcher to achieve a small improvement in response rates. For example, somewhat better response rates can be achieved by producing a survey that looks professional and is laid out in a pleasing manner, has a reading level that is not too difficult, and includes instructions that are easy to follow.

Past research has shown that response rates can be increased by:

1. Using personalization in correspondence such as inserting the person's name in the salutation or by having the researcher actually sign the letter in ink [2, 11, 21, 30, 45, 52, 54, 55, 70, 74.]

2. Sending a prenotification letter a week or two before the actual survey is sent out to 'warn' the respondent of their selection as a participant and to be on the look-out for the survey [1, 9, 27, 33, 39, 48, 54, 63, 65, 71, 75, 77, 80, 81].
3. Using deadlines in the respondent letters to give respondents a heightened sense of priority to respond. Soft deadlines such as 'please respond within the next two weeks so we don't have to send you a reminder' provides a push without preventing the researcher from sending a further reminder [34, 41, 51, 56, 64, 68, 76].
4. Using a questionnaire of modest length, say 10 to 20 pages, rather than an overly long surveys will improve response rates (see **Survey Questionnaire Design**). Research has produced mixed results concerning the length of a survey. Obviously shorter surveys are less burdensome; but longer surveys may communicate a greater sense of the importance of the research issue. In general, the recommendation is to include no more material than is necessary to address the central hypotheses of the research [4, 10, 12, 13, 57, 60, 73].

Mail surveys when used appropriately and conducted utilizing procedures that have been shown to improve response rates, offer an attractive alternative to more expensive telephone or in-person interviews.

Mallows' C_p Statistic

A common problem in applications of **multiple linear regression analysis** in the behavioral sciences is that of predictor subset selection [10]. The goal of subset selection, also referred to as **variable selection** (e.g., [4]) or **model selection** (e.g., [13]) is to choose a smaller subset of predictors from a relatively larger number that is available so that the resulting regression model is parsimonious, yet has good predictive ability [3, 4, 12]. The problem of subset selection arises, for example, when a researcher seeks a predictive model that cross-validates well (see **Cross-validation** and [1, 11]), or when there is redundancy amongst the predictors leading to multicollinearity [3].

There are several approaches to predictor subset selection, including forward selection, backward elimination, and stepwise regression [2, 10]. A fourth, 'all possible subsets' procedure fits all $2^k - 1$ distinct models to determine a best fitting model (BFM) on the basis of some statistical criterion. A number of such criteria for choosing a BFM can be considered [5], including R^2 , one of several forms of R^2 adjusted for the number of predictors [11], the mean squared error, or one of a number of criteria based on information theory (e.g., **Akaike's** criterion, [6]). Mallows' [8, 9] C_p statistic is one such criterion that is related to this latter class of indices.

For any model containing a subset of p predictors from the total number of k predictors, Mallows' C_p can be written as:

$$C_p = \frac{RSS_p}{MSE_k} + 2p - n \quad (1)$$

where RSS_p is the residual sum of squares for the p -variable model, MSE_k is the mean squared error for the full (k -variable) model, and n is sample size. As such, C_p indexes the mean squared error of prediction for 'subset' models relative to the full model with a penalty for inclusion of unimportant predictors [7]. Because MSE_k is usually estimated as $RSS_k/(n - k)$, C_p can also be written as:

$$C_p = (n - k) \frac{RSS_p}{RSS_k} + 2p - n \quad (2)$$

Note that if the R^2 for a p -variable model is substantially less than the R^2 for the full k -variable model (i.e., 'important' variables are excluded from the subset), RSS_p/RSS_k will be large compared to the situation in which the p -variable subset model includes all or most of the 'important' predictors. In this case, the RSS_p/RSS_k ratio approaches 1.00, and if the model is relatively parsimonious, a large 'penalty' (in the form of $2p$) is not invoked and C_p is small. Note, however, that for the full model, $p = k$ so that $RSS_p/RSS_k = 1$ and C_p necessarily $= p$. In practice, for models with $p < k$ predictors, variable subsets with lower C_p values (around p or less) indicate preferred subset models. It is commonly recommended to plot models' C_p as a function of p and choose the predictor subset with minimum C_p as the preferred subset model (see [3], [8], and [9] for examples).

Mantel–Haenszel Methods

Numerous studies within the behavioral sciences have attempted to determine the degree of association between an explanatory variable, called *factor* (e.g., treatments, potentially harmful exposure), and another variable that is assumed to be determined by or dependent upon the factor variable, called *response variable* (e.g., degree of improvement, state of health). Moreover, quite frequently, researchers wish to control the modulating effect of other variables, known as *stratification variables* or *covariables* (e.g., age, level of illness, gender), on the relationship between factor and response (see **Analysis of Covariance**). **Stratification** variables may be the result of the research design, as in a multicenter clinical trial, in which the strata correspond to the different hospitals where the treatments have been applied or of *a posteriori* considerations made after the study data have been obtained. In any case, when factor and response variables are reported on categorical measurement scales (see **Categorizing Data**), either nominal or ordinal, the resulting data can be summarized in **contingency tables**, and the methods based on the work of **Cochran** [4] and Mantel and Haenszel [16] are commonly used for their analysis. In a general way, it can be said that these methods provide measures and significance tests of two-way association that control for the effects of covariables. The null hypothesis (H_0) they test is that of ‘partial no-association’, which establishes that in each one of the strata of the covariable, the response variable is distributed randomly with respect to the levels of the factor. In the simplest case, both factor and response are dichotomous variables, and the data can be summarized in a set of Q contingency tables 2×2 (denoted by $Q : 2 \times 2$), where each table corresponds to a stratum or level of the covariable, or to each combination of levels in the case of there being several covariables (see **Two by Two Contingency Tables**). To establish notation, let n_{hij} denote the frequency count of observations occurring at the i th factor level (row), ($i = 1, \dots, R = 2$), the j th level of the response variable (column), ($j = 1, \dots, C = 2$), and the h th level of the covariable or stratum, ($h = 1, \dots, Q$). In Table 1, this notation is applied to a typical study on risk factors and state of health.

Table 1 The 2×2 contingency table for the h th stratum

Exposure status	Health status		Total
	Condition present	Condition absent	
Not exposed	n_{h11}	n_{h12}	$N_{h1\cdot}$
Exposed	n_{h21}	n_{h22}	$N_{h2\cdot}$
Total	$N_{h\cdot 1}$	$N_{h\cdot 2}$	$N_{h\cdot\cdot}$

In sets of tables 2×2 , Mantel–Haenszel (MH) statistics are asymptotic tests that follow a chi-squared distribution (see **Catalogue of Probability Density Functions**) with one degree of freedom (df) and that, in general, can be expressed thus:

$$\chi_{MH}^2 = \frac{\left(\sum_{h=1}^Q a - \sum_{h=1}^Q E(A) \right)^2}{\sum_{h=1}^Q \text{var}(A)}. \quad (1)$$

Here, a is the observed frequencies in one of the cells of the table, $E(A)$ is the frequencies expected under H_0 , and $\text{var}(A)$ is the variance of the frequencies expected under H_0 . All of this summed across the strata. The strategy used for testing H_0 is as simple as comparing the frequencies observed in the contingency table (n_{hij}) with the frequencies that could be expected in the case of there being no relationship between factor and response. Naturally, in order to carry out the test, we need to establish a probabilistic model that determines the probability of obtaining a under H_0 . According to the assumed probability model, $E(A)$ and $\text{var}(A)$ will adopt different forms. Mantel and Haenszel [16] conditioning on the row and column totals ($N_{h1\cdot}$, $N_{h2\cdot}$, $N_{h\cdot 1}$, and $N_{h\cdot 2}$), that is, taking those values as fixed, establish that, under H_0 , the observed frequencies in each table (n_{hij}) follow the multiple hypergeometric probability model (see **Catalogue of Probability Density Functions**):

$$\Pr(n_{hij} | H_0) = \frac{\prod_{i=1}^R N_{hi\cdot}! \prod_{j=1}^C N_{h\cdot j}!}{N_{h\cdot\cdot}! \prod_{i=1}^R \prod_{j=1}^C n_{hij}!}. \quad (2)$$

2 Mantel–Haenszel Methods

Furthermore, on assuming that the marginal totals $(N_{hi\cdot})$ and $(N_{h\cdot j})$ are fixed, this distribution can be expressed in terms of count n_{h11} alone, since it determines the rest of the cell counts (n_{h12} , n_{h21} , and n_{h22}). Under H_0 , the hypergeometric mean and variance of n_{h11} are $E(n_{h11}) = N_{h1\cdot}N_{h\cdot 1}/N_{h\cdot\cdot}$ and $\text{var}(n_{h11}) = N_{h1\cdot}N_{h2\cdot}N_{h\cdot 1}N_{h\cdot 2}/N_{h\cdot\cdot}^2(N_{h\cdot\cdot} - 1)$ respectively. We thus obtain the MH chi-squared test:

$$\chi_{\text{MH}}^2 = \frac{\left(\left| \sum_{h=1}^Q n_{h11} - \sum_{h=1}^Q E(n_{h11}) \right| - 0.5 \right)^2}{\sum_{h=1}^Q \text{var}(n_{h11})}. \quad (3)$$

Cochran [4], taking only the total sample in each stratum $(N_{h\cdot\cdot})$ as fixed and assuming a binomial distribution, proposed a statistic that was quite similar to χ_{MH}^2 . The Cochran statistic can be rewritten in terms of (3), eliminating from it the continuity correction (0.5) and substituting $\text{var}(n_{h11})$ by $\text{var}^*(n_{h11}) = N_{h1\cdot}N_{h2\cdot}N_{h\cdot 1}N_{h\cdot 2}/N_{h\cdot\cdot}^3$. The essential equivalence between the two statistics when we have moderate sample sizes in each stratum means that the techniques expressed here are frequently referred to as the *Cochran–Mantel–Haenszel methods*. Nevertheless, statistic (3) is preferable, since it only demands that the combined row sample sizes $(N_{i\cdot} = \sum_{h=1}^Q \sum_{j=1}^C n_{hij})$ be large (e.g., $N_{i\cdot} > 30$), while that of Cochran demands moderate to large sample sizes (e.g., $N_{h\cdot\cdot} > 20$) in each table. A more precise criterion in terms of sample demands [15] recommends applying χ_{MH}^2 only if the result of the expressions

$$\sum_{h=1}^Q E(n_{h11}) - \left[\sum_{h=1}^Q \max(0, N_{h1\cdot} - N_{h\cdot 2}) \right] \text{ and } \left[\sum_{h=1}^Q \min(N_{h\cdot 1}, N_{h1\cdot}) \right] - \sum_{h=1}^Q E(n_{h11}) \quad (4)$$

is over five. When the sample requirements are not fulfilled, either because of the small sample size or because of the highly skewed observed table margins, we will have to use exact tests, such as those of Fisher or Birch [1].

In the case of rejecting the H_0 at the α significance level (if $\chi_{\text{MH}}^2 \geq_{\text{df}(1)} \chi_{\alpha}^2$), the following step

is to determine the degree of association between factor and response. Among the numerous measures of association available for contingency tables (rate ratio, **relative risk**, **prevalence ratio**, etc.), Mantel and Haenszel [16] employed **odds ratios**. The characteristics of this measure of association is examined as follows. It should be noted that if the variables were independent, the *odds* of the probability (π) of responding in column 1 instead of column 2 (π_{h11}/π_{h12}) would be equal at all the levels of the factor. Therefore, the ratio of the odds, referred to as the *odds ratio* $\{\alpha = (\pi_{h11}/\pi_{h12})/(\pi_{h21}/\pi_{h22})\}$ or *cross-product ratio* ($\alpha = \pi_{h11}\pi_{h22}/\pi_{h12}\pi_{h21}$), will be 1. Assuming homogeneity of the odds ratios of each stratum ($\alpha_1 = \alpha_2 = \dots = \alpha_Q$), the MH measure of association calculated across all 2×2 contingency tables is the *common odds ratio estimator* ($\hat{\alpha}_{\text{MH}}$), given by

$$\hat{\alpha}_{\text{MH}} = \frac{\sum_{h=1}^Q R_h}{\sum_{h=1}^Q S_h} = \frac{\sum_{h=1}^Q n_{h11}n_{h22}/N_{h\cdot\cdot}}{\sum_{h=1}^Q n_{h12}n_{h21}/N_{h\cdot\cdot}}. \quad (5)$$

The range of $\hat{\alpha}_{\text{MH}}$ varies between 0 and ∞ . A value of 1 represents the hypothesis of no-association. If $1 < \hat{\alpha}_{\text{MH}} < \infty$, the first response is more likely in row 1 than in row 2; if $0 < \hat{\alpha}_{\text{MH}} < 1$, the first response is less likely in row 1 than in row 2. Because of the skewness of the distribution of $\hat{\alpha}_{\text{MH}}$, it is more convenient to use $\ln(\hat{\alpha}_{\text{MH}})$, the natural logarithm of $\hat{\alpha}_{\text{MH}}$. In this case, the independence corresponds to $\ln(\hat{\alpha}_{\text{MH}}) = 0$, the $\ln$ of the common odds ratio being symmetrical about this value. This means that, for $\ln(\hat{\alpha}_{\text{MH}})$, two values that are equal except for their sign, such as $\ln(2) = 0.69$ and $\ln(0.5) = -0.69$, represent the same degree of association. For constructing **confidence intervals** around $\hat{\alpha}_{\text{MH}}$, we need an estimator of its variance, and that which presents the best properties [12] is that of Robins, Breslow, and Greenland [18]:

$$\text{var}(\hat{\alpha}_{\text{MH}}) = \frac{(\hat{\alpha}_{\text{MH}})^2}{2} \frac{\sum_{h=1}^Q (P_h R_h)}{\left(\sum_{h=1}^Q R_h \right)^2}$$

$$+ \frac{\sum_{h=1}^Q (P_h S_h + Q_h R_h)}{\sum_{h=1}^Q R_h \sum_{h=1}^Q S_h} + \frac{\sum_{h=1}^Q Q_h S_h}{\left(\sum_{h=1}^Q S_h\right)^2}, \quad (6)$$

where $P_h = (n_{h11} + n_{h22})/N_{h..}$ and $Q_h = (n_{h12} + n_{h21})/N_{h..}$.

If we construct the intervals on the basis of $\ln(\hat{\alpha}_{MH})$, we must make the following adjustment: $\text{var}[\ln(\hat{\alpha}_{MH})] = \text{var}(\hat{\alpha}_{MH})/(\hat{\alpha}_{MH})^2$. Thus, the $100(1 - \alpha)\%$ confidence interval for $\ln(\hat{\alpha}_{MH})$ will be equal to $\ln(\hat{\alpha}_{MH}) \pm z_{\alpha/2} \sqrt{\text{var}[\ln(\hat{\alpha}_{MH})]}$. For $\hat{\alpha}_{MH}$, the $100(1 - \alpha)\%$ confidence limits will be equal to $\exp(\ln(\hat{\alpha}_{MH}) \pm z_{\alpha/2} \sqrt{\text{var}[\ln(\hat{\alpha}_{MH})]})$.

In relation to these aspects, it should be pointed out that nonfulfillment of the assumption of homogeneity of the odds ratios ($\alpha_1 = \alpha_2 = \dots = \alpha_Q$) does not invalidate $\hat{\alpha}_{MH}$ as a measure of association; even so, given that it is a weighted average of the stratum-specific odds ratios, it makes its interpretation difficult. In the case that the individual odds ratios differ substantially in direction, it is preferable to use the information provided by these odds ratios than to use $\hat{\alpha}_{MH}$. Likewise, nonfulfillment of the assumption of homogeneity does not invalidate χ^2_{MH} as a test of association, though it does reduce its statistical power [2]. Breslow and Day [3, 20] provide a test for checking the mentioned assumption (see **Breslow–Day Statistic**).

The statistics shown above are applied to the particular case of sets of contingency tables 2×2 . Fortunately, from the outset, various extensions have been proposed for these statistics [14, 16], all of them being particular cases of the analysis of sets of contingency tables with dimensions $Q : R \times C$. The

data structure for this general contingency table is shown in Table 2.

In the general case, the H_0 of no-association will be tested against different alternative hypotheses (H_1) that will be a function of the scale on which factor and response are measured. Thus, we shall have a variety of statistics that will serve for detecting the general association (both variables are nominal), mean score differences (factor is nominal and response ordinal), and linear correlation (both variables are ordinal).

The standard generalized Mantel–Haenszel test is defined, in terms of matrices, by Landis, Heyman, and Koch [13], as

$$Q_{GMH} = \left\{ \sum_{h=1}^Q (\mathbf{n}_h - \mathbf{m}_h)' \mathbf{A}_h' \right\} \left\{ \sum_{h=1}^Q \mathbf{A}_h \mathbf{V}_h \mathbf{A}_h' \right\}^{-1} \times \left\{ \sum_{h=1}^Q \mathbf{A}_h (\mathbf{n}_h - \mathbf{m}_h) \right\}, \quad (7)$$

where $\mathbf{n}_h$, $\mathbf{m}_h$, $\mathbf{V}_h$, and $\mathbf{A}_h$ are, respectively, the vector of observed frequencies, the vector of expected frequencies, the covariances matrix, and a matrix of linear functions defined in accordance with the H_1 of interest. From Table 2, these vectors are defined as $\mathbf{n}_h = (n_{h11}, n_{h21}, \dots, n_{hRC})'$; $\mathbf{m}_h = N_{h..}(\mathbf{p}_{h.*} \otimes \mathbf{p}_{h*})$, $\mathbf{p}_{h.*}$ and $\mathbf{p}_{h*}$ being vectors with the marginal row proportions ($p_{hi.} = N_{hi.}/N_{h..}$) and the marginal column proportions ($p_{h.j} = N_{h.j}/N_{h..}$), and $\otimes$ denoting the Kronecker product multiplication; $\mathbf{V}_h = N_{h..}^2/(N_{h..} - 1) \{(\mathbf{D}_{p_{h.*}} - \mathbf{p}_{h.*} \mathbf{p}_{h.*}') \otimes (\mathbf{D}_{p_{h*}} - \mathbf{p}_{h*} \mathbf{p}_{h*}')\}$, where $\mathbf{D}_{p_h}$ is a diagonal matrix with elements of the vector $\mathbf{p}_h$ on its main diagonal.

As it has been pointed out, depending on the measurement scale of factor and response, (7) will be resolved, via definition of the matrix $\mathbf{A}_h$ ($\mathbf{A}_h =$

Table 2 Data structure in the h th stratum

Factor levels	Response variable categories						Total
	1	2	·	j	·	C	
1	n_{h11}	n_{h12}	·	n_{h1j}	·	n_{h1C}	$N_{h1.}$
2	n_{h21}	n_{h22}	·	n_{h2j}	·	n_{h2C}	$N_{h2.}$
·	·	·	·	·	·	·	·
i	n_{hi1}	n_{hi2}	·	n_{hij}	·	n_{hiC}	$N_{hi.}$
·	·	·	·	·	·	·	·
R	n_{hR1}	n_{hR2}	·	n_{hRj}	·	n_{hRC}	$N_{hR.}$
Total	$N_{h.1}$	$N_{h.2}$	·	$N_{h.j}$	·	$N_{h.C}$	$N_{h..}$

$C_h \otimes R_h$), in a different statistic for detecting each H_1 . Briefly, these are as follows:

$Q_{GMH(1)}$. When the variable row and the variable column are nominal, the H_1 specifies that the distribution of the response variable differs in nonspecific patterns across levels of the row factor. Here, $R_h = [I_{R-1}, -J_{R-1}]$ and $C_h = [I_{C-1}, -J_{C-1}]$, where I_{R-1} is an identity matrix, and J_{R-1} is an $(R-1) \times 1$ vector of ones. Under H_0 , $Q_{GMH(1)}$ follows approximately a chi-squared distribution with $df = (R-1)(C-1)$.

$Q_{GMH(2)}$. When only the variable column is ordinal, the H_1 establishes that the mean responses differ across the factor levels, R_h being the same as that used in the previous case and $C_h = (c_{h1}, \dots, c_{hC})$, where c_{hj} is an appropriate score reflecting the ordinal nature of the j th category of response for the h th stratum. Selection of the values of C_h admits different possibilities that are well described in [13]. Under H_0 , $Q_{GMH(2)}$ has approximately a chi-squared distribution with $df = (R-1)$.

$Q_{GMH(3)}$. If both variables are ordinal, the H_1 establishes the existence of a linear progression (linear trend) in the mean responses across the levels of the factor (*see Trend Tests for Counts and Proportions*). In this case, C_h can be defined as the same as that for the mean responses difference and $R_h = (r_{h1}, \dots, r_{hR})$, where r_{hi} is an appropriate score reflecting the ordinal nature of the i th factor level for the h th stratum. Under H_0 , $Q_{GMH(3)}$ has approximately a chi-squared distribution with $df = 1$.

It should be noted how the successive H_1 s specify more and more restrictive patterns of association, so that each statistic increases the statistical power with respect to the previous ones for detecting its particular pattern of association. For example, $Q_{GMH(1)}$ can detect linear patterns of association, but it will do so with less power than $Q_{GMH(3)}$. Furthermore, the increase in power of $Q_{GMH(3)}$ compared to $Q_{GMH(1)}$ is achieved at the cost of an inability to detect more complex patterns of association. Obviously, when $C = R = 2$, $Q_{GMH(1)} = Q_{GMH(2)} = Q_{GMH(3)} = \chi_{MH}^2$, except for the lack of the continuity correction.

While MH methods have satisfactorily resolved the testing of the H_0 in the general case, to date

there is no estimator of the degree of association that is completely generalizable for $Q : R \times C$ tables. The interested reader can find generalizations, always complex, of $\hat{\alpha}_{MH}$ to $Q : 2 \times C$ tables ($C > 2$) in [10], [17], and [21].

The range of application of the methodology presented in this article is enormous, and it is widely used in epidemiology, **meta-analysis**, analysis of survival data (*see Survival Analysis*) (where it is known by the name of *logrank-test*), and psychometric research on differential item functioning [5–7, 9]. This is undoubtedly due to its simplicity and flexibility and due to its minimal demands for guaranteeing the validity of its results: on the one hand, it requires only that the sample size summed across the strata be sufficiently large for asymptotic results to hold (such that the MH test statistic can perfectly well be applied for matched **case-control studies** with only two subjects in each of the Q tables, as long as the number of tables is large); on the other hand, it permits the use of samples of convenience on not assuming a known sampling link to a larger reference population. This is possible, thanks to the fact that the H_0 of interest – that the distribution of the responses is random with respect to the levels of the factor – induces a probabilistic structure (the multiple hypergeometric distribution) that allows for judgment of its compatibility with the observed data without the need for external assumptions. Thus, it can be applied to **experimental designs**, group designs, and repeated-measures designs [12, 19, 22, 23], (*see Repeated Measures Analysis of Variance*) and also to designs based on observation or of a historical nature, such as **retrospective studies**, nonrandomized studies, or case–control studies [11], regardless of how the sampling was carried out. This undoubted advantage is offset by a disadvantage: given that the probability distributions employed are determined by the observed data (see (1)), the conclusions obtained will apply only to the sample under study. Consequently, generalization of the results to the target population should be based on arguments about the representativeness of the sample [11].

Example

We shall illustrate the use of the Mantel–Haenszel methods on the basis of the results of a survey on bullying and harassment at work (mobbing) carried out in Spain [8]. Table 3 shows the number of people

Table 3 Characteristics of mobbing victims

Gender	Job category	No bullying	bullied	Total	% bullied
Men	Manual	148	28	176	15.9
	Clerical	65	13	78	16.7
	Specialized technician	121	18	139	12.9
	Middle manager	95	7	102	6.9
	Manager/executive	29	2	31	6.5
Women	Manual	98	22	120	18.3
	Clerical	144	32	176	18.2
	Specialized technician	43	10	53	18.9
	Middle manager	38	7	45	15.6
	Manager/executive	8	1	9	11.1

in the survey who over a period of 6 months or more have been bullied at least once a week (bullied), and the number of those not fulfilling this criterion (no bullying).

In order to employ all the statistics considered, we shall analyze the data in different ways. Let us suppose that the main objective of the research is to determine whether there is a relationship between job category and mobbing. Moreover, as it is suspected that gender may be related to mobbing, we decided to control the effect of this variable. The result of applying the statistic χ^2_{MH} , without the continuity correction, to the following contingency table

	No bullying	Bullied	Total
Men	458	68	526
Women	331	72	403
Total	789	140	929

indicates the pertinence of this adjustment. Indeed, we find that χ^2_{MH} takes the value 4.34, which has

a p value of 0.037 with 1 df . Thus, assuming a significance level of .05, we reject the H_0 of ‘no partial association’ in favor of the alternative that suggests that bullying behavior is not distributed homogeneously between men and women. A value of 1.47 in $\hat{\alpha}_{MH}$ indicates that women have a higher probability of suffering mobbing than men do. The 95% confidence interval for the common odds ratio estimator, using the variance in (6) with a result of 0.07, is (1.02, 2.10). In the case of transforming $\hat{\alpha}_{MH}$ to the logarithmic scale [$\ln(\hat{\alpha}_{MH}) = 0.38$], the variance would equal 0.03, and the confidence interval, (0.022, 0.74). Note how $1.02 = \exp(0.02)$ and $2.10 = \exp(0.74)$. It should also be noted how our data satisfy the sample demands of the Mantel–Fleiss criterion (4): $\sum_{h=1}^1 E(n_{h11}) = 446.73$, $\sum_{h=1}^1 \max(0, 526 - 140) = 386$ and $\sum_{h=1}^1 \min(789, 526) = 526$, so that $(446.73 - 386) > 5$ and $(526 - 446.73) > 5$.

In line with the research objective, Table 4 shows the results of the Mantel–Haenszel statistics for association between job category and mobbing

Table 4 Results of the Mantel–Haenszel statistics with the respective linear operator matrices

Statistic	Value	df	p	$\mathbf{A}_h = \mathbf{C}_h \otimes \mathbf{R}_h$
$Q_{GMH(1)}$	5.74	4	.22	$[1 \ -1] \otimes \begin{bmatrix} 1 & 0 & 0 & 0 & -1 \\ 0 & 1 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 & -1 \\ 0 & 0 & 0 & 1 & -1 \end{bmatrix}$
$Q_{GMH(2)}$	5.74	4	.22	$[1 \ 2] \otimes \begin{bmatrix} 1 & 0 & 0 & 0 & -1 \\ 0 & 1 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 & -1 \\ 0 & 0 & 0 & 1 & -1 \end{bmatrix}$
$Q_{GMH(3)}$	4.70	1	.03	$[1 \ 2] \otimes [1 \ 2 \ 3 \ 4 \ 5]$

adjusted for gender; also shown is the linear operator matrix defined in accordance with the H_1 s of general association ($Q_{GMH(1)}$), mean row scores difference ($Q_{GMH(2)}$), and trend in mean scores ($Q_{GMH(3)}$).

Considering the data in Table 4, a series of points can be made. First point is that when the response variable is dichotomous, as is the case here, $Q_{GMH(1)}$ and $Q_{GMH(2)}$ offer the same results. Second is that if we suppose that both the response variable and the factor are ordinal variables, then there exists a statistically significant linear relationship ($p < .05$) between job category and level of harassment or bullying, once the effect of gender is controlled; more specifically, that the higher the level of occupation, the less bullying there is. Third point is that, as we can see, $Q_{GMH(3)}$ is the most powerful statistic, via reduction of df, for detecting the linear relationship between factor and response variable. Finally, we can conclude that almost 82% (4.70/5.74) of the nonspecific difference in mean scores can be explained by the linear tendency.

Note: The software for calculating the generalized Mantel-Haenszel statistics is available upon request from the author.

Marginal Independence

The definition of statistical independence is rather straightforward. Specifically, if $f(x,y|\theta)$ denotes the joint distribution of random variables X and Y , then the marginal distributions of X and Y can be written as $f(x|\theta) = \int f(x,y|\theta) dy$ and $f(y|\theta) = \int f(x,y|\theta) dx$, respectively, where θ is some parameter in the distribution functions, and in the discrete case one would use summation instead of integration (*see Contingency Tables*). Then the variables X and Y are independent if their joint distribution is the product of the two marginal distributions, $f(x,y|\theta) = f(x|\theta)f(y|\theta)$. The intuition here is that knowledge of one of the variables offers no knowledge of the other. Yet the simplicity of this definition belies the complexity that may arise when it is applied in practice.

For example, it may seem intuitively obvious that shoe size and intelligence should not be correlated or associated. That is, they should be independent. This may be true when considering a given cohort defined by age group, but when the age is allowed to vary, it is not hard to see that older children would be expected to have both larger feet and more education than younger children. This confounding variable, age, could then lead to the finding that children with larger shoe sizes appear to be more intelligent than children with smaller shoe sizes.

Conversely, one would expect height and weight to be positively associated, and not independent, because all things considered, taller individuals tend to also be heavier. However, this assumes that we are talking about the relation between height and weight among a set of distinct individuals. It is also possible to consider the relation between height and weight for a given individual over time. While many individuals will gain weight as they age and get taller over a period of years, one may also consider the relation between height and weight for a given individual over the period of one day. That is, the height and weight of a given individual can be measured every hour during a given day. Among these measurements, height and weight may be independent.

Finally, consider income and age. For any given individual who does not spend much time out of work, income would tend to rise over time, as the age also increases. As such, these two variables should have a positive association over time for a given

individual. Yet, to the extent that educational opportunities improve over time, a younger generation may have access to better paying positions than their older counterparts. This trend could compensate for, or even reverse, the association within individuals.

We see, then, that the association between two variables depends very much on the context, and so the context must always be borne in mind when discussing association, causality, or independence. In fact, it is possible to create the appearance of a positive relation, either unwittingly or otherwise, when in fact no association exists. Berkson [4] demonstrated that when two events are independent in a population at large, they become negatively associated in a subpopulation characterized by the requirement of one of these events. That is, imagine a trauma center that handles only victims of gun-shot wounds and victims of car accidents, and suppose that in the population at large the two are independent. Then the probability of having been shot would not depend on whether one has been in a car accident. However, if one wanted to over-sample the cases, and study the relationship between these two events in our hypothetical trauma center, then one might find a negative association due to the missing cell corresponding to neither event. See Table 1.

In the trauma center, there would be an empty upper-left cell, corresponding to neither the X -event nor the Y -event. That is, n_{11} would be replaced with zero, and this would create the appearance of a negative association when in fact none exists. It is also possible to intentionally create the appearance of such a positive association between treatment and outcome with strategic patient selection [2]. Unfortunately, there is no universal context, and marginal independence without consideration of covariates does not tell us much about association within levels defined by the covariates. Suppose, for example, that Table 1 turned out as shown in Table 2.

In Table 2 X and Y are marginally independent because each cell entry (50) can be expressed

Table 1 Creating dependence between variables X and Y

$x \backslash y$	0	1	Sum
0	$n_{11} = 0$	n_{12}	$n_{1+} = n_{12}$
1	n_{21}	n_{22}	n_{2+}
Sum	$n_{+1} = n_{21}$	n_{+2}	n_{++}

2 Marginal Independence

Table 2 Independence between variables X and Y

$y \backslash x$	0	1	Sum
0	50	50	100
1	50	50	100
Sum	100	100	200

Table 3 Independence between variables X and Y by gender

Males

$y \backslash x$	0	1	Sum
0	25	25	50
1	25	25	50
Sum	50	50	100

Females

$y \backslash x$	0	1	sum
0	25	25	50
1	25	25	50
Sum	50	50	100

as the product of its row and column proportions, and the grand total, 200. That is, $50 = (100/200)(100/200)(200)$. In general, for discrete variables, X and Y are marginally independent if $P(x, y) = P(x)P(y)$. But now consider a covariate. To illustrate, suppose that X is the treatment received, Y is the outcome, and Z is gender. From Table 2 we see that treatment and outcome are independent, but what does this really tell us? When gender is considered, the gender-specific tables may turn out to confirm this independence, as in Table 3.

In Table 3, each treatment is equally effective for each gender, with a 50% response rate. It is also possible that Table 2 conceals a true treatment*gender interaction, so that each treatment is better for one gender, and overall they compensate so as to balance out. Consider, for example, Table 4.

In Table 4, Treatment 0 is better for males, with a 60% response rate (compared to 40% for Treatment 1), but this is reversed for females. What may be more surprising is that, even with marginal independence, either treatment may still be better for all levels of the covariate. Consider, for example, Table 5.

In Table 5 we see that more males take Treatment 0 (62%), more females take Treatment 1 (62%), and

Table 4 Compensating dependence between variables X and Y by gender

Males

$y \backslash x$	0	1	Sum
0	20	30	50
1	30	20	50
Sum	50	50	100

Females

$y \backslash x$	0	1	Sum
0	30	20	50
1	20	30	50
Sum	50	50	100

Table 5 Separation of variables X and Y by gender

Males

$y \backslash x$	0	1	Sum
0	18	2	20
1	44	36	80
Sum	62	38	100

Females

$y \backslash x$	0	1	Sum
0	32	48	80
1	6	14	20
Sum	38	62	100

males have a better response rate than females for either treatment (44/62 vs. 6/38 for Treatment 0, and 36/38 vs. 14/62 for Treatment 1). However, it is also apparent that Treatment 1 is more effective than Treatment 0, both for males (36/38 vs. 44/62) and females (14/62 vs. 6/38). Such reinforcing effects can be masked when the two tables are combined to form Table 2; this is possible precisely because more of the better responders (males) took the worse treatment (Treatment 0), thereby making it look better than it should relative to the better treatment (Treatment 1). See [1], **Paradoxes** and [3] for more information regarding Simpson's paradox (*see Two by Two Contingency Tables*). Clearly, different conclusions might be reached from the same data, depending on whether the marginal table or the partial tables are considered.

Marginal Models for Clustered Data

Introduction

Clustered data commonly arise in studies in the behavioral sciences. For example, clustered data arise when observations are obtained on children nested within schools. Other common examples of naturally occurring clusters in the population are households, clinics, medical practices, and neighborhoods. Longitudinal and repeated measures studies (*see* **Longitudinal Data Analysis** and **Repeated Measures Analysis of Variance**) also give rise to clustered data. The main feature of clustered data that needs to be accounted for in any analysis is the fact that units from the same cluster are likely to respond in a more similar manner than units from different clusters. This **intracluster correlation** invalidates the crucial assumption of independence that is the cornerstone of so many standard statistical techniques. As a result, the straightforward application of standard regression models (e.g., **multiple linear regression** for a continuous response or **logistic regression** for a binary response) to clustered data is no longer valid unless some allowance for the clustering is made.

There are a number of ways to extend regression models to handle clustered data. All of these procedures account for the within-cluster correlation among the responses, though they differ in approach. Moreover, the method of accounting for the within-cluster association has important implications for the interpretation of the regression coefficients in models for discrete response data (e.g., binary data or counts). The need to distinguish models according to the interpretation of their regression coefficients has led to the use of the terms ‘marginal models’ and ‘mixed effects models’; the former are often referred to as ‘population-average models’, the latter as ‘cluster-specific models’ (see [3, 6, 8]). In this article, we focus on marginal models for clustered data; the meaning of the term ‘marginal’, as used in this context, will soon be apparent.

Marginal Models

Marginal models are primarily used to make inferences about population means. A distinctive feature

of marginal models is that they separately model the mean response and the within-cluster association among the responses. The goal is to make inferences about the former, while the latter is regarded as a nuisance characteristic of the data that must be accounted for to make correct inferences about the population mean response. The term *marginal* in this context is used to emphasize that we are modeling each response within a cluster separately and that the model for the mean response depends only on the covariates of interest, and not on any random effects or on any of the other responses within the same cluster. This is in contrast to *mixed effects models* where the mean response depends not only on covariates but also on random effects (*see* **Generalized Linear Mixed Models; Hierarchical Models**).

In our discussion of marginal models, the main focus is on discrete response data, for example, binary responses and counts. However, it is worth stressing that marginal models can be applied equally to continuous response data. Before we describe the main features of marginal models, we need to introduce some notation for clustered data. Let i index units within a cluster and j index clusters. We let Y_{ij} denote the response on the i th unit within the j th cluster; the response can be continuous, binary, or a count. For example, Y_{ij} might be the outcome for the i th individual in the j th clinic or the i th repeated measurement on the j th subject. Associated with each Y_{ij} is a collection of p covariates, $X_{ij1}, \dots, X_{ijp}$. We can group these into a $p \times 1$ vector denoted by $X_{ij} = (X_{ij1}, \dots, X_{ijp})'$. A marginal model has the following three-part specification:

- (1) The conditional mean of each response, denoted by $\mu_{ij} = E(Y_{ij}|X_{ij})$, is assumed to depend on the p covariates through a known ‘link function’,

$$g(\mu_{ij}) = \beta_0 + \beta_1 X_{ij1} + \beta_2 X_{ij2} + \dots + \beta_p X_{ijp}. \quad (1)$$

The link function applies a known transformation to the mean, $g(\mu_{ij})$, and then links the transformed mean to a linear combination of the covariates (*see* **Generalized Linear Models (GLM)**).

2 Marginal Models for Clustered Data

- (2) Given the covariates, the variance of each Y_{ij} is assumed to depend on the mean according to

$$\text{Var}(Y_{ij}|X_{ij}) = \phi v(\mu_{ij}), \quad (2)$$

where $v(\mu_{ij})$ is a known ‘variance function’ (i.e., a known function of the mean, μ_{ij}) and ϕ is a scale parameter that may be known or may need to be estimated.

- (3) The within-cluster association among the responses, given the covariates, is assumed to be a function of additional parameters, α (and also depends upon the means, μ_{ij}).

In less technical terms, marginal models take a suitable transformation of the mean response (e.g., a logit transformation for binary responses or a log transformation for count data) and relate the transformed mean response to the covariates. Note that the model for the mean response allows each response within a cluster to depend on covariates but not on any random effects or on any of the other responses within the same cluster. The use of nonlinear link functions, for example, $\log(\mu_{ij})$, ensures that the model produces predictions of the mean response that are within the allowable range. For example, when analyzing a binary response, μ_{ij} has interpretation in terms of the probability of ‘success’ (with $0 < \mu_{ij} < 1$). If the mean response, here the probability of success, is related directly to a linear combination of the covariates, the regression model can yield predicted probabilities outside of the range from 0 to 1. The use of certain nonlinear link functions, for example, $\text{logit}(\mu_{ij})$, ensures that this cannot happen.

This three-part specification of a marginal model can be considered a natural extension of **generalized linear models**. Generalized linear models are a collection of regression models for analyzing diverse types of univariate responses (e.g., continuous, binary, counts). They include as special cases the standard linear regression and **analysis of variance** (ANOVA) models for a normally distributed continuous response, logistic regression models for a binary response, and **log-linear models** or Poisson regression models for counts (see **Generalized Linear Models (GLM)**). Although generalized linear models encompass a much broader range of regression models, these three are among the most widely used regression models in applications. Marginal models can be thought of as extensions

of generalized linear models, developed for the analysis of independent observations, to the setting of clustered data. The first two parts correspond to the standard generalized linear model, albeit with no distributional assumptions about the responses. It is the third component, the incorporation of the within-cluster association among the responses, that represents the main extension of generalized linear models. To highlight the main components of marginal models, we consider some examples using the three-part specification given earlier.

Example 1. Marginal model for counts Suppose that Y_{ij} is a count and we wish to relate the mean count (or expected rate) to the covariates. Counts are often modeled as Poisson random variables (see **Catalogue of Probability Density Functions**), using a log link function. This motivates the following illustration of a marginal model for Y_{ij} :

- (1) The mean of Y_{ij} is related to the covariates through a log link function,

$$\log(\mu_{ij}) = \beta_0 + \beta_1 X_{ij1} + \beta_2 X_{ij2} + \cdots + \beta_p X_{ijp}. \quad (3)$$

- (2) The variance of each Y_{ij} , given the effects of the covariates, depends on the mean response,

$$\text{Var}(Y_{ij}|X_{ij}) = \phi \mu_{ij}, \quad (4)$$

where ϕ is a scale parameter that needs to be estimated.

- (3) The within-cluster association among the responses is assumed to have an exchangeable correlation (or equi-correlated) pattern,

$$\text{Corr}(Y_{ij}, Y_{i'j}|X_{ij}, X_{i'j}) = \alpha \text{ (for } i \neq i'), \quad (5)$$

where i and i' index two distinct units within the j th cluster.

The marginal model specified above is a log-linear regression model (see **Log-linear Models**), with an extra-Poisson variance assumption. The within-cluster association is specified in terms of a single correlation parameter, α . In this example, the extra-Poisson variance assumption allows the variance to be inflated (relative to Poisson variability) by a factor ϕ (when $\phi > 1$). In many applications, count data have variability that far exceeds that predicted by

the Poisson distribution; a phenomenon referred to as *overdispersion*.

Example 2. Marginal model for a binary response

Next, suppose that Y_{ij} is a binary response, taking values of 0 (denoting ‘failure’) or 1 (denoting ‘success’), and it is of interest to relate the mean of Y_{ij} , $\mu_{ij} = E(Y_{ij}|X_{ij}) = \Pr(Y_{ij} = 1|X_{ij})$, to the covariates. The distribution of each Y_{ij} is Bernoulli (*see Catalogue of Probability Density Functions*) and the probability of success is often modeled using a logit link function. Also, for a Bernoulli random variable, the variance is a known function of the mean. This motivates the following illustration of a marginal model for Y_{ij} :

- (1) The mean of Y_{ij} , or probability of success, is related to the covariates by a logit link function,

$$\text{logit}(\mu_{ij}) = \log\left(\frac{\mu_{ij}}{1 - \mu_{ij}}\right) = \beta_0 + \beta_1 X_{ij1} + \beta_2 X_{ij2} + \cdots + \beta_p X_{ijp}. \quad (6)$$

- (2) The variance of each Y_{ij} depends only on the mean response (i.e., $\phi = 1$),

$$\text{Var}(Y_{ij}|X_{ij}) = \mu_{ij}(1 - \mu_{ij}). \quad (7)$$

- (3) The within-subject association among the vector of repeated responses is assumed to have an exchangeable log odds ratio pattern,

$$\log \text{OR}(Y_{ij}, Y_{i'j}|X_{ij}, X_{i'j}) = \alpha, \quad (8)$$

where

$$\begin{aligned} & \text{OR}(Y_{ij}, Y_{i'j}|X_{ij}, X_{i'j}) \\ &= \frac{\Pr(Y_{ij} = 1, Y_{i'j} = 1|X_{ij}, X_{i'j}) \times \Pr(Y_{ij} = 0, Y_{i'j} = 0|X_{ij}, X_{i'j})}{\Pr(Y_{ij} = 1, Y_{i'j} = 0|X_{ij}, X_{i'j}) \times \Pr(Y_{ij} = 0, Y_{i'j} = 1|X_{ij}, X_{i'j})}. \end{aligned} \quad (9)$$

The marginal model specified above is a logistic regression model, with a Bernoulli variance assumption, $\text{Var}(Y_{ij}|X_{ij}) = \mu_{ij}(1 - \mu_{ij})$. An exchangeable within-cluster association is specified in terms of pairwise log odds ratios rather than correlations, a natural metric of association for binary responses (*see Odds and Odds Ratios*).

These two examples are purely illustrative. They demonstrate how the choices of the three components of a marginal model might differ according to the type of response variable. However, in principle, any suitable link function can be chosen and alternative assumptions about the variances and within-cluster associations can be made.

Finally, our description of marginal models does not require distributional assumptions for the observations, only a regression model for the mean response. In principle, this three-part specification of a marginal model can be extended by making full distributional assumptions about the responses within a cluster. For discrete data, the joint distribution requires specification of the mean vector and pairwise (or two-way) associations, as well as the three-, four- and higher-way associations among the responses (see, for example, [1, 2, 4]). Furthermore, as the number of responses within a cluster increases, the number of association parameters proliferates rapidly. In short, with discrete data there is no simple analog of the multivariate normal distribution (*see Catalogue of Probability Density Functions*). As a result, specification of the joint distribution for discrete data is inherently difficult and **maximum likelihood estimation** can be computationally difficult except in very simple cases. Fortunately, assumptions about the joint distribution are not necessary for estimation of the parameters of the marginal model. The avoidance of distributional assumptions leads to a method of estimation known as *generalized estimating equations* (GEE) (*see Generalized Estimating Equations (GEE)*). The GEE approach provides a convenient alternative to maximum likelihood estimation for estimating the parameters of marginal models (see [5, 7]) and has been implemented in many of the commercially available statistical software packages, for example, SAS, Stata, S-Plus, SUDAAN, and GenStat (*see Software for Statistical Analyses*).

Contrasting Marginal and Mixed Effects Models

A crucial aspect of marginal models is that the mean response and within-cluster association are modeled separately. This separation has important implications for interpretation of the regression coefficients. In particular, the regression coefficients in the model for the mean have *population-averaged* interpretations.

4 Marginal Models for Clustered Data

That is, the regression coefficients describe the effects of covariates on the mean response, where the mean response is *averaged* over the clusters that comprise the target population; hence, they are referred to as *population-averaged* effects. For example, the regression coefficients might have interpretation in terms of contrasts of the overall mean responses in certain subpopulations (e.g., different intervention groups).

In contrast, *mixed effects models* account for clustering in the data by assuming there is natural heterogeneity across clusters in a subset of the regression coefficients. Specifically, a subset of the regression coefficients are assumed to vary across clusters according to some underlying distribution; these are referred to as *random effects* (see **Fixed and Random Effects**). The correlation among observations within a cluster arises from their sharing of common random effects. Although the introduction of random effects can simply be thought of as a means of accounting for the within-cluster correlation, it has important implications for the interpretation of the regression coefficients. Unlike marginal models, the regression coefficients in mixed effects models have cluster-specific, rather than population-averaged, interpretations. That is, due to the nonlinear link functions (e.g., logit or log) that are usually adopted for discrete responses, the regression coefficients in mixed effects models describe covariate effects on the mean response for a typical cluster.

The subtle distinctions between these two classes of models for clustered data can be illustrated in the following example based on a pre-post study design with a binary response (e.g., denoting ‘success’ or ‘failure’). Suppose individuals are measured at baseline (pretest) and following an intervention intended to increase the probability of success (posttest). The ‘cluster’ is comprised of the pair of binary responses obtained on the same individual at baseline and post-baseline. These clustered data can be analyzed using a mixed effects logistic regression model,

$$\text{logit}\{E(Y_{ij}|X_{ij}, b_j)\} = \beta_0^* + \beta_1^* X_{ij} + b_j, \quad (10)$$

where b_j is normally distributed, with mean zero and variance, σ_b^2 . The single covariate in this model takes values $X_{ij} = 0$ at baseline and $X_{ij} = 1$ post-baseline (see **Dummy Variables**). In this mixed effects model, β_0^* and β_1^* are the *fixed effects* and b_j is the *random effect*. This model assumes that individuals

(or clusters) differ in terms of their underlying propensity for success; this heterogeneity is expressed in terms of the variability of the random effect, b_j . For a ‘typical’ individual from the population (where a ‘typical’ individual can be thought of as one with unobserved random effect $b_j = 0$, the center of the distribution of b_j), the log odds of success at baseline is β_0^* ; the log odds of success following the intervention is $\beta_0^* + \beta_1^*$.

The log odds of success at baseline and postbaseline are displayed in Figure 1, for the case where $\beta_0^* = -1.75$, $\beta_1^* = 3.0$, and $\sigma_b^2 = 1.5$. At baseline, the log odds has a normal distribution with mean and median of -1.75 (see the unshaded density for the log odds in Figure 1). From Figure 1 it is clear that there is heterogeneity in the odds of success, with approximately 95% of individuals having a baseline log odds of success that varies from -4.15 to 0.65 (or $-1.75 \pm 1.96\sqrt{1.5}$). When the odds of success is translated to the probability scale (see vertical axis of

Figure 1 Subject-specific probability of success as a function of subject-specific log odds of success at baseline (unshaded densities) and post-baseline (shaded densities). Solid lines represent medians of the distributions; dashed lines represent means of the distributions.

Figure 1),

$$\begin{aligned} E(Y_{ij}|X_{ij}, b_j) &= \Pr(Y_{ij} = 1|X_{ij}, b_j) \\ &= \frac{e^{\beta_0^* + \beta_1^* X_{ij} + b_j}}{1 + e^{\beta_0^* + \beta_1^* X_{ij} + b_j}}, \end{aligned} \quad (11)$$

the baseline probability of success for a typical individual (i.e., an individual with $b_j = 0$) from the population is 0.148 (or $e^{-1.75}/1 + e^{-1.75}$). Furthermore, approximately 95% of individuals have a baseline probability of success that varies from 0.016 to 0.657.

From Figure 1 it is transparent that the symmetric, normal distribution for the baseline log odds of success does not translate into a corresponding symmetric, normal distribution for the probability of success. Instead, the subject-specific probabilities have a positively skewed distribution with median, but not mean, of 0.148 (see solid line in Figure 1). Because of the skewness, the mean of the subject-specific baseline probabilities is pulled towards the tail and is equal to 0.202 (see dashed line in Figure 1). Thus, the probability of success for a ‘typical’ individual from the population (0.148) is not the same as the prevalence of success in the same population (0.202), due to the nonlinearity of the relationship between subject-specific probabilities and log odds. Similarly, although the log odds of success postbaseline has a normal distribution (see the shaded density for the log odds in Figure 1), the subject-specific post-baseline probabilities have a negatively skewed distribution with median, but not mean, of 0.777 (see solid line in Figure 1). Because of the skewness, the mean is pulled towards the tail and is equal to 0.726 (see dashed line in Figure 1).

Figure 1 highlights how the effect of intervention on the log odds of success for a typical individual (or cluster) from the population, $\beta_1^* = 3.0$, is not the same as the contrast of population log odds. The latter is what is estimated in a marginal model, say

$$\text{logit}\{E(Y_{ij}|X_{ij})\} = \beta_0 + \beta_1 X_{ij}, \quad (12)$$

and can be obtained by comparing or contrasting the log odds of success in the population at baseline, $\log(0.202/0.798) = -1.374$, with the log odds of success in the population postbaseline, $\log(0.726/0.274) = 0.974$. This yields a *population-averaged* measure of effect, $\beta_1 = -2.348$, which is approximately 22% smaller than β_1^* , the *subject-specific* (or *cluster-specific*) effect of intervention.

This simple example highlights how the choice of method for accounting for the within-cluster association has consequences for the interpretation of the regression model parameters.

Summary

Marginal models are widely used for the analysis of clustered data. They are most useful when the focus of inference is on the overall population mean response, averaged over all the clusters that comprise the population. The distinctive feature of marginal models is that they model each response within the cluster separately. They assume dependence of the mean response on covariates but not on any random effects or other responses within the same cluster. This is in contrast to mixed effects models where the mean response depends not only on covariates but on random effects.

There are a number of important distinctions between marginal and mixed effects models that go beyond simple differences in approaches to accounting for the within-cluster association among the responses. In particular, these two broad classes of regression models have somewhat different targets of inference and have regression coefficients with distinct interpretations. In general, the choice of method for analyzing discrete clustered data cannot be made through any automatic procedure. Rather, it must be made on subject-matter grounds. Different models for discrete clustered data have somewhat different targets of inference and thereby address subtly different scientific questions regarding the dependence of the mean response on covariates.

Markov Chain Monte Carlo and Bayesian Statistics

Introduction

Bayesian inference (*see* **Bayesian Statistics**) differs from classical inference in treating parameters as random variables, one consequence being probability values on hypotheses, and confidence intervals on parameters (or ‘credible intervals’ for Bayesians), that are concordant with commonsense interpretations [31]. Thus, in the Bayesian paradigm, credible intervals are areas under the probability distributions of the parameters involved. Despite inferential and philosophical advantages of this kind, practical application of Bayesian methods was formerly prohibited by the need for numerical integration, except in straightforward problems with a small number of parameters. This problem has been overcome in the last 15 years by the advent of simulation methods known as Markov Chain Monte Carlo (MCMC) algorithms; *see* [2, 21, 49]. MCMC sample-based estimation methods overcome problems associated with numerical procedures that were in use in the 1980s. They can handle high-dimensional problems and explore the distributions of parameters, regardless of the forms of the distributions of the likelihood and the parameters. Using MCMC methods, one can obtain compute posterior summary statistics (means, variances, 95% intervals) for parameters or other structural quantities. Starting from postulated or ‘prior’ distributions of the parameters, improved or ‘posterior’ estimates of the distributions are obtained by randomly sampling from parameter distributions in turn and updating the parameter values until stable distributions are generated.

The implementation of these methods has resulted in Bayesian methods actually being easier to apply than ‘classical’ methods to some complex problems with large numbers of parameters, for example, those involving multiple random effects (*see* **Generalized Linear Mixed Models**) [6]. Such methods are now available routinely via software such as WINBUGS (*see* the page at <http://www.mrc-bsu.ac.uk> for programs and examples). Bayesian data analysis (especially via modern MCMC methods) has

a range of other advantages such as the ability to combine inferences over different models when no model is preeminent in terms of fit (‘model averaging’) and permitting comparisons of fit between nonnested models. By contrast, classical hypothesis testing is appropriate for testing nested models that differ only with respect to the inclusion/exclusion of particular parameters.

Bayesian inference can be seen as a process of learning about parameters. Thus, Bayesian learning does not undertake statistical analysis in isolation but draws on existing knowledge in prior framing of the model, which can be quite important (and beneficial) in clinical, epidemiological, and health applications [48, Chapter 5]. The estimation process then combines existing evidence with the actual study data at hand. The result can be seen as a form of evidence accumulation. Prior knowledge about parameters and updated knowledge about them are expressed in terms of densities: the data analysis converts existing knowledge expressed in a *prior* density to updated knowledge expressed in a *posterior* density (*see* **Bayesian Statistics**). The Bayesian analysis also produces predictions (e.g., the predicted response for new values of independent variables, as in the case of predicting a relapse risk for a hypothetical patient with an ‘average’ profile). It also provides information about functions of parameters and data (e.g., a ratio of two regression coefficients). One may also assess hypotheses about parameters (e.g., that a regression coefficient is positive) by obtaining a posterior probability relating to the hypothesis being true.

Modern sampling methods also allow for representing densities of parameters that may be far from Normal (e.g., skew or multimodal), whereas **maximum likelihood estimation** and classical tests rely on asymptotic Normality approximations under which a parameter has a symmetric density. In addition to the ease with which exact densities of parameters (i.e., possibly asymmetric) are obtained, other types of inference may be simplified by using the sampling output from an MCMC analysis. For example, a hypothesis that a regression parameter is positive is assessed by the proportion of iterations where the sampled value of the parameter is positive. Bayesian methods are advantageous for random effects models in which ‘pooling strength’ acts to provide more reliable inferences about individual cases. This has relevance in applications such as multilevel

analysis (*see* **Generalized Linear Mixed Models**) and **meta-analysis** in which, for example, institutions or treatments are being compared. A topical UK illustration relates to a Bayesian analysis of child surgery deaths in Bristol, summarized in a Health Department report [16]; *see* [40].

Subsequent sections consider modern Bayesian methods and inference procedures in more detail. We first consider the principles of Bayesian methodology and the general principles of MCMC estimation. Then, sampling algorithms are considered as well as possible ‘problems for the unwary’ in terms of convergence and identifiability raised when models become increasingly complex. We next consider issues of prior specification (a distinct feature of the Bayes approach) and questions of model assessment. A worked example using data on drug regimes for schizophrenic patients involves the question of missing data: this frequently occurs in **panel studies** (in the form of ‘attrition’), and standard approaches such as omitting subjects with missing data lead to biased inference.

Bayesian Updating

In more formal terms, the state of existing knowledge about a parameter, or viewed another way, a statement about the uncertainty about a parameter set $\theta = (\theta_1, \theta_2, \dots, \theta_d)$ is expressed in a prior density $p(\theta)$. The likelihood of a particular set of data y , given θ , is denoted $p(y|\theta)$. For example, the standard constant variance linear regression (*see* **Multiple Linear Regression**) with p predictors (including the intercept) involves a Normal likelihood with $\theta = (\beta, \sigma^2)$, where β is a vector of length p and σ^2 is the error variance. The updated or posterior uncertainty about θ , having taken account of the data, is expressed in the density $p(\theta|y)$. From the usual conditional probability rules (*see* **Probability: An Introduction**), this density can be written

$$p(\theta|y) = \frac{p(\theta, y)}{p(y)}. \quad (1)$$

Applying conditional probability again gives

$$p(\theta|y) = \frac{p(y|\theta)p(\theta)}{p(y)}. \quad (2)$$

The divisor $p(y)$ is a constant and the updating process therefore takes the form

$$p(\theta|y) \propto p(y|\theta)p(\theta). \quad (3)$$

This can be stated as ‘the posterior is proportional to likelihood times prior’ or, in practical terms, updated knowledge about parameters combines existing knowledge with the sample data at hand.

The Place of MCMC Methods

The genesis of estimation via MCMC sampling methods lies in the need to obtain expectations of, or densities for, functions of parameters $g(\theta)$, and of model predictions z , that take account of the information in both the data and the prior. Functions $g(\theta)$ might, for instance, be differences in probabilities of relapse under different treatments, where the probabilities are predicted by a **logistic regression** or the total of sensitivity and specificity, sometimes known as the *Youden Index* [10]. These are standard indicators of the effectiveness of screening instruments, for example [33]; the sensitivity is the proportion of cases correctly identified and the specificity is the probability that the test correctly identifies that a healthy individual is disease free.

The expectation of $g(\theta)$ is obtained by integrating over the posterior density for θ

$$E_{\theta|y}[g(\theta)] = \int g(\theta)p(\theta|y) d\theta, \quad (4)$$

while the density for future observations (‘replicate data’) is

$$p(z|y) = \int p(z|\theta, y)p(\theta|y) d\theta. \quad (5)$$

Often, the major interest is in the marginal densities of the parameters themselves, where the marginal density of the j th parameter θ_j is obtained by integrating out all other parameters

$$p(\theta_j|y) = \int p(\theta|y) d\theta_1 d\theta_2 \dots d\theta_{j-1} d\theta_{j+1} \dots d\theta_d. \quad (6)$$

Such expectations or densities may be obtained analytically for conjugate analyses such as a binomial likelihood where the probability has a beta prior (*see* **Catalogue of Probability Density Functions**). (A conjugate analysis occurs when the prior and posterior densities for θ_j have the same form, e.g., both Normal or both beta.) Results can be obtained by asymptotic approximations [5], or by analytic approximations [34]. Such approximations are not appropriate for posteriors that are non-Normal or

where there is multimodality. An alternative strategy facilitated by contemporary computer technology is to use sampling-based approximations based on the Monte Carlo principle. The idea here is to use repeated sampling to build up a picture of marginal densities such as $p(\theta_j|y)$: modal values of the density will be sampled most often, those in the tails relatively infrequently.

The Monte Carlo method in general applications assumes a sample of independent simulations $u^{(1)}, u^{(2)} \dots u^{(T)}$ from a density $p(u)$, whereby $E[g(u)]$ is estimated as

$$\bar{g}_T = \frac{\sum_{t=1}^T g(u^{(t)})}{T}. \quad (7)$$

However, in MCMC applications, independent sampling from the posterior target density $p(\theta|y)$ is not typically feasible. It is valid, however, to use dependent samples $\theta^{(t)}$, provided the sampling satisfactorily covers the support of $p(\theta|y)$ [28]. MCMC methods generate pseudorandom-dependent draws from probability distributions such as $p(\theta|y)$ via Markov chains. Sampling from the Markov chain converges to a stationary distribution, namely, $\pi(\theta) = p(\theta|y)$, if certain requirements on the chain are satisfied, namely irreducibility, aperiodicity, and positive recurrence¹; see [44]. Under these conditions, the average $\bar{g}_T$ tends to $E_\pi[g(u)]$ with probability 1 as $T \rightarrow \infty$, despite dependent sampling. Remaining practical questions include establishing an MCMC sampling scheme and establishing that convergence to a steady state has been obtained [14].

MCMC Sampling Algorithms

The Metropolis–Hastings (M–H) algorithm [29] is the baseline for MCMC sampling schemes. Let $\theta^{(t)}$ be the current parameter value in an MCMC sampling sequence. The M–H algorithm assesses whether a move to a potential new parameter value θ^* should be made on the basis of the transition probability

$$\alpha(\theta^*|\theta^{(t)}) = \min \left(1, \frac{p(\theta^*|y)f(\theta^{(t)}|\theta^*)}{p(\theta^{(t)}|y)f(\theta^*|\theta^{(t)})} \right). \quad (8)$$

The density f is known as a proposal or jumping density. The rate at which a proposal generated by f is accepted (the acceptance rate) depends on how

close θ^* is to $\theta^{(t)}$ and this depends on the variance σ^2 assumed in the proposal density. For a Normal proposal density, a higher acceptance rate follows from reducing σ^2 but with the risk that the posterior density will take longer to explore. If the proposal density is symmetric $f(\theta^{(t)}|\theta^*) = f(\theta^*|\theta^{(t)})$, then the M–H algorithm reduces to an algorithm used by Metropolis et al. [41] for indirect simulation of energy distributions, whereby

$$\alpha(\theta^*|\theta^{(t)}) = \min \left[1, \frac{p(\theta^*|y)}{p(\theta^{(t)}|y)} \right]. \quad (9)$$

While it is possible for the proposal density to relate to the entire parameter set, it is often computationally simpler to divide θ into blocks or components, and use componentwise updating.

Gibbs sampling is a special case of the componentwise M–H algorithm, whereby the proposal density for updating θ_j is the full conditional density $f_j(\theta_j|\theta_{k \neq j})$, so that proposals are accepted with probability 1. This sampler was originally developed by Geman and Geman [24] for Bayesian image reconstruction, with its full potential for simulating marginal distributions by repeated draws recognized by Gelfand and Smith [21]. The Gibbs sampler involves parameter-by-parameter updating, which when completed forms the transition from $\theta^{(t)}$ to $\theta^{(t+1)}$:

1. $\theta_1^{(t+1)} \sim f_1(\theta_1|\theta_2^{(t)}, \theta_3^{(t)}, \dots, \theta_d^{(t)});$
2. $\theta_2^{(t+1)} \sim f_2(\theta_2|\theta_1^{(t+1)}, \theta_3^{(t)}, \dots, \theta_d^{(t)});$
- d. $\theta_d^{(t+1)} \sim f_d(\theta_d|\theta_1^{(t+1)}, \theta_3^{(t+1)}, \dots, \theta_{d-1}^{(t+1)}).$

Repeated sampling from M–H samplers such as the Gibbs sampler generates an autocorrelated sequence of numbers that, subject to regularity conditions (ergodicity, etc.), eventually ‘forgets’ the starting values $\theta^{(0)} = (\theta_1^{(0)}, \theta_2^{(0)}, \dots, \theta_d^{(0)})$ used to initialize the chain and converges to a stationary sampling distribution $p(\theta|y)$.

Full conditional densities can be obtained by abstracting out from the full model density (likelihood times prior) those elements including θ_j and treating other components as constants [26]. Consider a conjugate model for Poisson count data y_i with means μ_i that are themselves gamma distributed. This is a model appropriate for overdispersed count data with actual variability $\text{var}(y)$ exceeding that under

the Poisson model. This sort of data often occurs because of variations in frailty, susceptibility, or ability between subjects; a study by Bockenholt et al. provides an illustration involving counts of emotional experiences [7]. Thus, neuroticism is closely linked to proneness to experience unpleasant emotions, while extraversion is linked with sociability, enthusiasm, and pleasure arousal: hence, neuroticism and extraversion are correlated with counts of intense unpleasant and pleasant emotions. For example, $y_i \sim Po(\mu_i t_i)$ might be the numbers of emotions experienced by a particular person in a time interval t_i and μ_i the average emotion count under the model. Suppose variations in proneness follow a gamma density $\mu_i \sim Ga(\alpha, \beta)$, namely,

$$f(\mu_i|\alpha, \beta) = \frac{\mu_i^{\alpha-1} e^{-\beta\mu_i} \beta^\alpha}{\Gamma(\alpha)} \quad (10)$$

and further that $\alpha \sim E(a)$, $\beta \sim Ga(b, c)$, where a , b , and c are preset constants; this prior structure is used by George et al. [25]. The posterior density $p(\theta|y)$, of $\theta = (\mu_1, \dots, \mu_n, \alpha, \beta)$ given y , is then proportional to

$$e^{-a\alpha} \beta^{b-1} e^{-c\beta} \left[\frac{\beta^\alpha}{\Gamma(\alpha)} \right]^n \left[\prod_{i=1}^n e^{-\mu_i t_i} \mu_i^{y_i} \mu_i^{\alpha-1} e^{\beta\mu_i} \right],$$

since all constants (such as the denominator $y_i!$ in the Poisson likelihood) are included in the proportionality constant. The conditional densities of μ_i and β are $f_1(\mu_i|\alpha, \beta) = Ga(y_i + \alpha, \beta + t_i)$ and $f_2(\beta|\alpha, \mu_i) = Ga(b + n\alpha, c + \Sigma\mu_i)$ respectively, while that of α is

$$f_3(\alpha|\beta, \mu) \propto e^{-a\alpha} \left[\frac{\beta^\alpha}{\Gamma(\alpha)} \right]^n \left(\prod_{i=1}^n \mu_i \right)^{\alpha-1}. \quad (11)$$

This density is nonstandard but log-concave and cannot be sampled directly. However, adaptive rejection sampling [27] may be used. By contrast, sampling from the gamma densities for μ_i and β is straightforward. For a Gibbs sampling MCMC application, we would repeatedly sample $\mu_i^{(t+1)}$ from f_1 conditional on $\alpha^{(t)}$ and $\beta^{(t)}$, then $\beta^{(t+1)}$ from f_2 conditional on $\mu_i^{(t+1)}$ and $\alpha^{(t)}$, and $\alpha^{(t+1)}$ from f_3 conditional on $\mu_i^{(t+1)}$ and $\beta^{(t+1)}$. By repeated sampling of $\mu_i^{(t)}$, $\alpha^{(t)}$, and $\beta^{(t)}$, for iterations $t = 1, \dots, T$, we approximate the marginal densities of these parameters, with the approximation improving as T increases.

Convergence and Identifiability

There are many unresolved questions around the assessment of convergence of MCMC sampling procedures [14]. It is preferable to use two or more parallel chains with diverse starting values to ensure full coverage of the sample space of the parameters, and to diminish the chance that the sampling will become trapped in a small part of the space [23]. Single long runs may be adequate for straightforward problems, or as a preliminary to obtain inputs to multiple chains. Convergence for multiple chains may be assessed using Gelman–Rubin scale reduction factors (SRF) that compare variation in the sampled parameter values within and between chains. Parameter samples from poorly identified models will show wide divergence in the sample paths between different chains and variability of sampled parameter values between chains will considerably exceed the variability within any one chain. In practice, SRFs under 1.2 are taken as indicating convergence.

Analysis of sequences of samples from an MCMC chain amounts to an application of time-series methods, in regard to problems such as assessing stationarity in an autocorrelated sequence. Autocorrelation at lags 1, 2, and so on may be assessed from the full set of sampled values $\theta^{(t)}$, $\theta^{(t+1)}$, $\theta^{(t+2)}$, $\dots$, or from subsamples K steps apart $\theta^{(t)}$, $\theta^{(t+K)}$, $\theta^{(t+2K)}$, $\dots$, and so on. If the chains are mixing satisfactorily, then the autocorrelations in the $\theta^{(t)}$ will fade to zero as the lag increases (e.g., at lag 10 or 20). High autocorrelations that do not decay mean that less information about the posterior distribution is provided by each iteration and a higher sample size T is necessary to cover the parameter space.

Problems of convergence in MCMC sampling may reflect problems in model identifiability due to overfitting or redundant parameters. Choice of diffuse priors increases the chance of poorly identified models, especially in complex hierarchical models or small samples [20]. Elicitation of more informative priors or application of parameter constraints may assist identification and convergence. Slow convergence will show in poor ‘mixing’ with high autocorrelation between successive sampled values of parameters, and trace plots that wander rather than rapidly fluctuating around a stable mean. Conversely, running multiple chains often assists in diagnosing poor identifiability of models. Correlation between parameters tends to delay convergence

and increase the dependence between successive iterations. Reparameterization to reduce correlation – such as centering predictor variables in regression – usually improves convergence [22].

Choice of Prior

Choice of the prior density is an important issue in Bayesian inference, as inferences may be sensitive to the choice of prior, though the role of the prior may diminish as sample size increases. From the viewpoint of a subject-matter specialist, the prior is the way to include existing subject-matter knowledge and ensure the analysis is ‘evidence consistent’. There may be problems in choosing appropriate priors for certain types of parameters: variance parameters in random effects models are a leading example [15].

A long running (and essentially unresolvable) debate in Bayesian statistics revolves around the choice between objective ‘off-the-shelf’ priors, as against ‘subjective’ priors that may include subject-matter knowledge. There may be a preference for off-the-shelf or reference priors that remove any subjectivity in the analysis. In practice, just proper but still diffuse priors are a popular choice (see the WINBUGS manuals for several examples), and a sensible strategy is to carry out a sensitivity analysis with a range of such priors. Just proper priors are those that still satisfy the conditions for a valid density: they integrate to 1, whereas ‘improper’ priors do not. However, they are diffuse in the sense of having a large variance that does not contain any real information about the location of the parameter.

Informative subjective priors based on elicited opinion from scientific specialists, historical studies, or the weight of established evidence, can also be justified. One may even carry out a preliminary evidence synthesis using forms of meta-analysis to set an informative prior; this may be relevant for treatment effects in clinical studies or disease prevalence rates [48]. Suppose the unknown parameter is the proportion π of parasuicide patients making another suicide attempt within a year of the index event. There is considerable evidence on this question, and following a literature review, a prior might be set with the mean recurrence rate 15%, and 95% range between 7.5 and 22.5%. This corresponds approximately to a beta prior with parameters 7.5 and 42.5. A set of previous representative studies might be used

more formally in a form of meta-analysis, though if there are limits to the applicability of previous studies to the current target population, the information from previous studies may be down-weighted in some way. For example, the precision of an estimated relative risk or prevalence rate from a previous study may be halved. A diffuse prior on π might be a $\text{Be}(1,1)$ prior, which is in fact equivalent to assuming a proportion uniformly distributed between 0 and 1.

Model Comparison and Criticism

Having chosen a prior and obtained convergence for a set of alternative models, one is faced with choosing between models (or possibly combining inferences over them) and with diagnostic checking (e.g., assessing outliers). Several methods have been proposed for model choice and diagnosis based on Bayesian principles. These include many features of classical model assessment such as penalizing complexity and requiring accurate predictions (i.e., cross-validation). To develop a Bayesian adaptation of frequentist model choice via the AIC, Spiegelhalter et al. [47] propose estimating the effective total number of parameters or model dimension, d_e . Thus, d_e is the difference between the mean $\bar{D}$ of the sampled deviances $D^{(t)}$ and the deviance $D(\bar{\theta}|y)$ at the parameter posterior mean $\bar{\theta}$. This total is generally less than the nominal number of parameters in complex hierarchical random effects models (see **Generalized Linear Mixed Models**). The deviance information criterion is then $\text{DIC} = D(\bar{\theta}|y) + 2d_e$. Congdon [12] considers repeated parallel sampling of models to obtain the density of $\Delta\text{DIC}_{jk} = \text{DIC}_j - \text{DIC}_k$ for models j and k .

Formal Bayesian model assessment is based on updating prior model probabilities $P(M_j)$ to posterior model probabilities $P(M_j|Y)$ after observing the data. Imagine a scenario to obtain probabilities of a particular model being true, given a set of data Y , and assuming that one of J models, including the model in question, is true; or possibly that truth resides in averaging over a subset of the J models. Then

$$P(M_j|Y) = \frac{[P(M_j)P(Y|M_j)]}{\sum_{j=1}^J [P(M_j)P(Y|M_j)]}, \quad (12)$$

where $P(Y|M_j)$ are known as marginal likelihoods. Approximation methods for $P(Y|M_j)$ include those

presented by Gelfand and Dey [19], Newton and Raftery [42], and Chib [8]. The Bayes factor is used for comparing one model against another under the formal approach and is the ratio of marginal likelihoods

$$B_{12} = \frac{P(Y|M_1)}{P(Y|M_2)}. \quad (13)$$

Congdon [13] considers formal choice based on Monte Carlo estimates of $P(M_j|Y)$ without trying to approximate marginal likelihoods.

Whereas data analysis is often based on selecting a single best model and making inferences as if that model were true, such an approach neglects uncertainty about the model itself, expressed in the posterior model probabilities $P(M_j|Y)$ [30]. Such uncertainty implies that for closely competing models, inferences should be based on model-averaged estimates

$$E[g(\theta)] = \sum_j P(M_j|Y)g(\theta_j|y). \quad (14)$$

Problems with formal Bayes model choice, especially in complex models or when priors are diffuse, have led to alternative model-assessment procedures, such as those including principles of predictive cross-validation; see [18, 35].

Bayesian Applications in Psychology and Behavioral Sciences

In psychological and behavioral studies, the methods commonly applied range from clinical trial designs with individual patients as subjects to population based ecological studies. The most frequent analytic frameworks are **multivariate analysis** and **structural equation models** (SEMs), more generally, latent class analysis (LCA), diagnosis and classification studies (*see Discriminant Analysis; k-means Analysis*), and panel and **case-control studies**. Bayesian applications to psychological data analysis include SEM, LCA, and item response analysis, see [3, 9, 37, 38, 46]; and factor analysis per se [1, 4, 36, 43, 45]. Here we provide a brief overview of a Bayesian approach to missing data in panel studies, with a worked example using the WINBUGS package (code available at www.geog.qmul.ac.uk/staff/congdon.html). This package presents great analytic flexibility while leaving issues such as choice of sampling methods to an inbuilt expert system [11].

An Illustrative Application

Panel studies with data y_{it} on subjects i at times t are frequently subject to attrition (permanent loss from observation from a given point despite starting the study), or intermittently missing responses [32]. Suppose that some data are missing in a follow-up study of a particular new treatment due to early patient withdrawal. One may wonder whether this loss to observation is ‘informative’, for instance, if early exit is due to adverse consequences of the treatment. The fact that some patients do withdraw generates a new form of data, namely, binary indicators $r_{it} = 1$ when the response y_{it} is missing, and $r_{it} = 0$ when a response is present. If a subject drops out permanently at time t , they contribute to the likelihood at that point with an observation $r_{it} = 1$, but are not subsequently included in the model. If withdrawal is informative, then the probability that an exit occurs (the probability that $r = 1$) is related to y_{it} . However, this value is not observed if the patient exits, raising the problem that a model for $\Pr(r = 1)$ has to be in terms of a hypothetical value, namely, the value for y_{it} that would have been observed had the response actually happened [39]. This type of missing data mechanism is known as missingness not at random (MNAR) (*see Missing Data*).

By contrast, if missingness is random (often written as MAR, or missingness at random), then $\Pr(r_{it} = 1)$ may depend on values of observed variables, such as preceding y values ($y_{i,t-1}$, $y_{i,t-2}$, etc.), but not on the values of possibly missing variables such as y_{it} itself. Another option is missingness completely at random (abbreviated as MCAR), when none of the data collected or missing is relevant to explaining the chance of missingness (*see Missing Data*). Only in this scenario is complete case analysis valid.

In concrete modeling terms, in the MCAR model, missingness at time t is not related to any other variable, whereas in the informative model missingness could be related to any other variable, missing, or observed. Suppose we relate the probability π_{it} that $r_{it} = 1$ to current and preceding values of the response y and to a known covariate x (e.g., time in the trial). Then,

$$\text{logit}(\pi_{it}) = \eta_1 + \eta_2 y_{it} + \eta_3 y_{i,t-1} + \eta_4 x_{it} + \eta_5 x_{i,t-1} \quad (15)$$

Under the MNAR scenario, dropout at time t (causing r_{it} to be 1) may be related to the possibly

missing value of y_{it} at that time. This would mean that the current value of y influences the chance that $r = 1$ (i.e., $\eta_2 \neq 0$). Note that y_{it} is an extra unknown when $r_{it} = 1$ (i.e., the hypothetical missing value is imputed or ‘augmented’ under the model). Under a MAR scenario, by contrast, previous observed values of y , or current/preceding x may be relevant to the chance of a missing value, but the current value of y is not relevant. So η_3, η_4 , and η_5 may be nonzero but one would expect $\eta_2 = 0$. Finally, MCAR missingness would mean $\eta_2 = \eta_3 = \eta_4 = \eta_5 = 0$.

To illustrate how dropout might be modeled in panel studies, consider a longitudinal trial comparing a control group with two drug treatments for schizophrenia, haloperidol, and risperidone [17]. The response y_{it} was the Positive and Negative Symptom Scale (PANSS), with higher scores denoting more severe illness, and obtained at seven time points (selection, baseline, and at weeks 1, 2, 4, 6, and 8). Let v_t denote the number of weeks, with the baseline defined by $v_2 = 0$, and selection into the study by $v_1 = -1$. Cumulative attrition is only 0.6% at baseline but reaches 1.7%, 13.5%, 23.6%, and 39.7% in successive waves, reaching 48.5% in the final wave. The question is whether attrition is related to health status: if the dropout rate is higher for those with high PANSS scores (e.g., because they are gaining no benefit from their treatment), then observed time paths of PANSS scores are in a sense unrepresentative.

Let treatment be specified by a trichotomous indicator G_i (control, haloperidol, risperidone). We assume the data are Normal with $y_{it} \sim N(\mu_{it}, \sigma^2)$. If subject i drops out at time $t = t^*$, then $r_{it^*} = 1$ at that time but the person is excluded from the model for times $t > t^*$. The model for μ_{it} includes a grand mean M , main treatment effects $\delta_j (j = 1 \dots 3)$, linear and quadratic time effects, θ_j and γ_j , both specific to treatment j , and random terms over both subjects and individual readings:

$$\mu_{it} = M + \delta_{Gi} + \theta_{Gi}v_t + \gamma_{Gi}v_t^2 + U_i + e_{it}. \quad (16)$$

Since the model includes a grand mean, a corner constraint $\delta_1 = 0$ is needed for identifiability. The U_i are subject level indicators of unmeasured morbidity factors, sometimes called ‘permanent’ random effects. The model for e_{it} allows for dependence over time (autocorrelation), with an allowance also for the unequally spaced observations (the gap between

observations is sometimes 1 week, sometimes 2). Thus,

$$e_{it} \sim N(\rho^{[v_t - v_{t-1}]}e_{i,t-1}, \sigma_e^2). \quad (17)$$

We take ρ , the correlation between errors one week apart, to be between 0 and 1. Note that the model for y also implicitly includes an uncorrelated error term with variance σ^2 .

The dropout models considered are more basic than the one discussed above. Thus, two options are considered. The first option is a noninformative (MAR) model allowing dependence on preceding (and observed) $y_{i,t-1}$ but not on the current, possibly missing, y_{it} . So

$$\text{logit}(\pi_{it}) = \eta_{11} + \eta_{12}y_{i,t-1}. \quad (18)$$

The second adopts the alternative informative missingness scenario (MNAR), namely,

$$\text{logit}(\pi_{it}) = \eta_{21} + \eta_{22}y_{it} \quad (19)$$

since this allows dependence on (possibly missing) contemporaneous scores y_{it} . We adopt relatively diffuse priors on all the model parameters (those defining μ_{it} and π_{it}), including $N(0, 10)$ priors on δ_j and θ_j and $N(0, 1)$ priors on γ_j .

With the noninformative dropout model, similar results to those cited by Diggle [17, p. 221] are obtained (see Table 1). Dropout increases with PANSS score under the first dropout model (the coefficient η_{12} is clearly positive with 95% CI restricted to positive values), so those remaining in the trial are increasingly ‘healthier’ than the true average, and so increasingly unrepresentative. The main treatment effect for risperidone, namely δ_3 , has a negative mean (in line with the new drug producing lower average PANSS scores over all observation points) but its 95% interval is not quite conclusive. The estimates for the treatment-specific linear trends in PANSS scores (θ_1, θ_2 , and θ_3) do, however, conclusively show a fall under risperidone, and provide evidence for the effectiveness of the new drug. The quadratic effect for risperidone reflects a slowing in PANSS decline for later observations. Note that the results presented in Table 1 constitute ‘posterior summaries’ in a very simplified form.

Introducing the current PANSS score y_{it} into the model for response r_{it} makes the dropout model informative. The fit improves slightly under the predictive criterion [35] based on comparing replicate

Table 1 PANSS model parameters, alternative dropout models

	Noninformative			Informative		
	Mean	2.5%	97.5%	Mean	2.5%	97.5%
Response model						
η_{11}	-5.32	-5.84	-4.81			
η_{12}	0.034	0.028	0.039			
η_{21}				-5.58	-6.28	-4.80
η_{22}				0.034	0.026	0.041
Observation model						
Main treatment effect						
δ_2	1.43	-1.95	5.02	3.32	-0.95	7.69
δ_3	-1.72	-4.29	1.49	-4.66	-8.63	-0.66
Autocorrelation parameter						
ρ	0.94	0.91	0.97	0.96	0.93	0.99
Linear time effects						
θ_1	0.04	-1.29	1.48	0.06	-0.61	0.68
θ_2	1.03	-0.11	2.25	1.15	0.38	1.88
θ_3	-1.86	-2.40	-1.16	-0.81	-1.16	-0.42
Quadratic time effects						
γ_1	-0.066	-0.258	0.117	-0.017	-0.186	0.158
γ_2	-0.066	-0.232	0.095	0.046	-0.135	0.240
γ_3	0.104	0.023	0.175	0.108	0.023	0.199

data z_{it} to actual data y_{it} . The parameter η_{22} has a 95% CI confined to positive values and suggests that missingness may be informative; to conclusively establish this, one would consider more elaborate dropout models including both y_{it} , earlier y values, $y_{i,t-1}$, $y_{i,t-2}$, and so on, and possibly treatment group too. In terms of inferences on treatment effectiveness, both main treatment and linear time effects for risperidone treatment are significantly negative under the informative model, though the time slope is less acute.

Note that maximum likelihood analysis is rather difficult for this type of problem. In addition to the fact that model estimation depends on imputed y_{it} responses when $r_{it} = 1$, it can be seen that the main effect treatment parameters under the first dropout model have somewhat skewed densities. This compromises classical significance testing and derivation of confidence limits in a maximum likelihood (ML) analysis. To carry out analysis via classical (e.g., ML) methods for such a model requires technical knowledge and programming skills beyond those of the average psychological researcher. However, using a Bayes approach, it is possible to apply this method for a fairly unsophisticated user of WINBUGS. Note that the original presentation of the informative analysis via classical methods

does not include parameter standard errors [17, Table 9.5], whereas obtaining full parameter summaries (which are anyway more extensive than simply means and standard errors) is unproblematic via MCMC sampling.

As an example of a relatively complex hypothesis test that is simple under MCMC sampling, consider the probability that $\delta_3 < \min(\delta_1, \delta_2)$, namely, that the main treatment effect (in terms of reducing the PANSS score) under risperidone is greater than either of the other two treatments. This involves inserting a single line in WINBUGS, namely,

```
test.del <- step(min(delta[1],
                      delta[2]) - delta[3])
```

and monitoring the proportion of iterations where the condition $\delta_3 < \min(\delta_1, \delta_2)$ holds. Under the informative dropout model, we find this probability to be .993 (based on the second half of a two-chain run of 10 000 iterations), whereas for the noninformative dropout model it is .86 (confirming the inconclusive nature of inference on the parameter δ_3 under this model). Such flexibility in hypothesis testing is one feature of Bayesian sampling estimation via MCMC.

As a postscript, we can say that the current ‘state of play’ on simulation-based estimation leaves much

scope for development. We can see that MCMC has brought a revolution to the implementation of Bayesian inference and this is likely to continue as computing speeds continue to improve. Our analysis has demonstrated the ease of determining posterior distributions in complex applications, and of developing significance tests that allow for skewness and other non-Normality. These, among other benefits of MCMC techniques, are discussed in a number of accessible books, for example [3, 28].

Note

1. Suppose a chain is defined on a space S . A chain is irreducible if for any pair of states $(s_i, s_j) \in S$ there is a nonzero probability that the chain can move from s_i to s_j in a finite number of steps. A state is positive recurrent if the number of steps the chain needs to revisit the state has a finite mean. If all its states are positive recurrent, then the chain itself is positive recurrent. A state has period k if it can only be revisited after a number of steps that is a multiple of k . Otherwise, the state is aperiodic. If all its states are aperiodic, then the chain itself is aperiodic. Positive recurrence and aperiodicity together constitute ergodicity.

Markov Chain Monte Carlo Item Response Theory Estimation

Introduction

Item response theory (IRT) (*see* **Item Response Theory (IRT) Models for Polytomous Response Data; Item Response Theory (IRT) Models for Rating Scale Data**) postulates the probability of a correct response to an item, given a person's underlying ability level, θ . There are many types of item response models, all of which are designed to model different testing situations. However, all of these models contain parameters that characterize the items, and parameters that characterize the examinee. For these models to be useful, the item and person parameters need to be estimated from item response data.

Traditionally, joint **maximum likelihood** (JML) and marginal maximum likelihood (MML) procedures have been used to estimate item parameters (*see* **Maximum Likelihood Estimation**). MML has been favored over JML as the JML estimates are not consistent [8]. The MML estimates proved to be very robust, and have performed well for the traditional models. However, the need for new models is growing, as testing practices become more sophisticated. As model complexity increases, so does the estimation of the model parameters. Therefore, a need for different estimation methods is necessary if model development is to continue, since the MML procedure is not feasible for estimating all models. Fortunately, with the advancements in technology, different estimation methods have become possible. As a result, several new models have been developed to meet the growing needs of measurement. Among the more popular models are the testlet response model [2, 17, 18] and the hierarchical rater model [12, 15]. Both of these models have employed Markov Chain Monte Carlo (MCMC) methods for estimating item parameters (*see* **Markov Chain Monte Carlo and Bayesian Statistics**).

MCMC procedures are becoming more popular among psychometricians primarily due to its flexibility. As noted above, new problems that were previously too difficult, or even impossible, to solve with the traditional methods can be solved. In concept, the

idea of MCMC estimation is to simulate a sample from the posterior distribution of the parameters, and to use the sample to obtain point estimates of the parameters. Since some (most) posterior distributions are difficult to sample from directly, modifications can be made to the process to allow for sampling from a more convenient distribution (e.g., normal), yet selecting the values from that distribution that could realistically have come from the posterior distribution of interest. Any distribution may be used provided that the range of that distribution is chosen appropriately [4]. The drawback to MCMC techniques is the time it often takes to provide a solution. The amount of time it takes depends on many factors, including the choice of the distribution, and some analyses can take weeks of computer time! However, as computing power continues to grow, so will the ease of implementing MCMC methods. As such, it is a technique that will likely gain even more popularity than it enjoys today.

Initial research into MCMC for estimating IRT parameters began with the traditional models, for which MML estimates were available. First, dichotomous models were studied [1, 10, 11, 13], and then this methodology was extended to polytomous models [9, 14, 19]. By doing so, comparisons between estimates obtained with MML and MCMC could be compared, and the MCMC procedures appear to produce estimates similar to those found using MML. As these models are relatively simple, MCMC for IRT parameters will be discussed using these models. The general principles can be applied to estimating parameters of more complex models.

Markov Chain Monte Carlo

Before describing the details of Markov Chain Monte Carlo estimation, a brief description of Markov chains and the introduction of some terminology are necessary.

Markov Chains

A **Markov chain** can be thought of as a system that evolves through various stages, and, at any given stage, exists in a certain state. A Markov chain is a system where the state that the system exists at any stage is determined solely based on probabilities. Further, if a Markov chain is in a particular state

2 Markov Chain Monte Carlo IRT Estimation

at a given stage, the probability that in the next stage it will be at a given state depends only on the present state, and not on past states. That is, at stage k , the probability that it exists in a given state in stage $k+1$ depends only on the state of the chain at stage k , and not stages $1 \dots k-1$. The probabilities of going to the various states are termed the *transition probabilities* and are assumed known. Given that there are typically multiple states that the Markov chain can inhabit at a given stage, the *transition matrix* provides the transition probabilities of going from one state to any other state. That is, the p_{ij} element of the matrix is the probability of going from state i to state j . A distinguishing feature of a Markov chain is that these probabilities do not change over time.

Notation and Terminology

Let $s_i^{(m)}$ denote the probability that the Markov chain is in state i after m transitions. Supposing that there are n different states, there are n such probabilities. These probabilities can be organized into an $n \times 1$ vector, which will be referred to as the *state vector* of the Markov chain. After each transition, a new state vector is formed. As the chain must be in *some* state at any given stage, the sum of the elements of each state vector must be one.

As a Markov chain progresses, the state vectors may tend to converge to a vector of probabilities, say S . Therefore, for a ‘suitably large’ number of transitions, it is reasonable to assume $S_m = S$. This vector S is referred to as the *steady state vector*, or *stationary vector*, for the Markov chain. That is, the vector S provides the long-term probability that the chain will be in each of the various states. In order for the Markov chain to converge to a unique steady-state vector, some regularity conditions must be met: The transition matrix, P , must be a stochastic matrix, that is, the sum of any row is one, and for some integer m , P^m has every entry in the matrix positive.

Markov Chain Monte Carlo Estimation

The basic idea behind MCMC estimation is to create a Markov chain consisting of states $M_0, M_1, M_2, \dots$, where $M_k = (\theta^k, \beta^k)$, and θ, β are the unknown IRT parameters. The chain is created so that the stationary distribution, $\pi(\theta, \beta)$, to which the chain

converges, is the posterior distribution, $p(\theta, \beta|X)$, where X is the matrix of item response data. States (observations) from the Markov chain are simulated and inferences about the parameters are made based on these observations.

The behavior of the Markov chain is determined by its transition kernel $t[(\theta^0, \beta^0), (\theta^1, \beta^1)] = P[M_{k+1} = (\theta^1, \beta^1) | M_k = (\theta^0, \beta^0)]$, which is the probability of moving to a new state, (θ^1, β^1) , given that the current state is (θ^0, β^0) [13]. The stationary distribution $\pi(\theta, \beta)$ satisfies

$$\int_{\theta, \beta} t[(\theta^0, \beta^0), (\theta^1, \beta^1)] \pi(\theta^0, \beta^0) d(\theta^0, \beta^0) = \pi(\theta^1, \beta^1) [13] \quad (1)$$

If we can define the transition kernel such that the stationary distribution, $\pi(\theta, \beta)$, is equal to the posterior distribution, $p(\theta, \beta|X)$, then, after a suitably large number of transitions, m , the remaining observations of the Markov chain behave as if from the posterior distribution. The first m observations are discarded, and are often referred to as the ‘burn-in’ [13]. The observations from the stationary distribution can then be considered a sample from the posterior distribution, and estimates of parameters can be obtained using sample statistics. Given this simple outline of Markov chain techniques, methods for creating the appropriate Markov chain are needed. There are several methods for generating the Markov chains. The most widely used include Gibbs sampling and the Metropolis–Hastings (M–H) algorithm within Gibbs. Each of these methods will be discussed next.

Gibbs Sampling. It was shown by Geman and Geman [6] that the transition kernel

$$t_G[(\theta^0, \beta^0), (\theta^1, \beta^1)] = p(\theta^1 | \beta^0, X) p(\beta^1 | \theta^1, X) \quad (2)$$

has stationary distribution $\pi(\theta, \beta) = p(\theta, \beta|X)$. A Markov chain with a transition kernel constructed in this manner is called a *Gibbs sampler*; the factors $p(\theta^1 | \beta^0, X)$, and $p(\beta^1 | \theta^1, X)$ are the complete conditional distributions of the model. Observations from the Gibbs sampler (θ^k, β^k) are simulated by repeated sampling from the complete conditional distributions. Therefore, to go from $(\theta^{k-1}, \beta^{k-1})$ to (θ^k, β^k) , two transition steps are required:

1. Draw $\theta^k \sim p(\theta|X, \beta^{k-1})$
2. Draw $\beta^k \sim p(\beta|X, \theta^k)$

Hence, the Gibbs sampler employs the standard IRT technique: Estimate one set of parameters holding the other as fixed, and known.

It can be noted that both $p(\theta|X, \beta)$ and $p(\beta|X, \theta)$ are proportional to the joint distribution $p(X, \theta, \beta) = p(X|\theta, \beta)p(\theta, \beta)$:

$$p(\theta|X, \beta) = \frac{p(X|\theta, \beta)p(\theta, \beta)}{\int p(X|\theta, \beta)p(\theta, \beta) d\theta}$$

and

$$p(\beta|X, \theta) = \frac{p(X|\theta, \beta)p(\theta, \beta)}{\int p(X|\theta, \beta)p(\theta, \beta) d\beta} \quad (3)$$

Assuming independence of θ, β , we can write this as $p(\theta|X, \beta) \propto p(X|\theta, \beta)p(\theta)$ and $p(\beta|X, \theta) \propto p(X|\theta, \beta)p(\beta)$. Setting up a Gibbs sampler requires computing the normalizing constants, $\int p(X|\theta, \beta)p(\theta, \beta)d\theta$, $\int p(X|\theta, \beta)p(\theta, \beta)d\beta$, which can be computationally complex. However, there are techniques available in MCMC to circumvent these calculations. One popular choice is to use the Metropolis–Hastings algorithm within Gibbs sampling.

Metropolis–Hastings within Gibbs. As discussed above, both Gibbs samplings yield Markov chains having the desired stationary distribution, $p(\theta, \beta|X)$. However, since it is not trivial to sample from any general distribution, the Gibbs sampler is modified by using the Metropolis–Hastings algorithm, which allows the user to specify a proposal distribution, which is easier to sample from than the complete conditional distributions, and to employ a rejection sampling technique that discards draws from the proposal distribution, which are unlikely to also be draws from the desired conditional distribution. By doing so, a chain with the same stationary distribution can be produced [16]. The Gibbs sampler is modified by choosing proposal distributions for each transition step instead of directly sampling from the complete conditional distributions. The M–H within Gibbs sampling uses different proposal distributions, $g_\theta(\theta^0, \theta^1)$ and $g_\beta(\beta^0, \beta^1)$ for each transition step:

1. Attempt to draw $\theta^k \sim p(\theta|\beta^{k-1}, X)$:
 - (a) Draw $\theta^* \sim g_\theta(\theta^{k-1}, \theta)$.
 - (b) Accept $\theta^k = \theta^*$ with probability

$$\alpha(\theta^{k-1}, \theta^*) = \min \left\{ \frac{p(X|\theta^*, \beta^{k-1})p(\theta^*, \beta^{k-1}) \times g_\theta(\theta^*, \theta^{k-1})}{p(X|\theta^{k-1}, \beta^{k-1})p(\theta^{k-1}, \beta^{k-1}) \times g_\theta(\theta^{k-1}, \theta^*)}, 1 \right\} \quad (4)$$

otherwise set $\theta^k = \theta^{k-1}$

2. Attempt to draw $\beta^k \sim p(\beta|\theta^k, X)$:
 - (a) Draw $\beta^* \sim g_\beta(\beta^{k-1}, \beta)$.
 - (b) Accept $\beta^k = \beta^*$ with probability

$$\alpha(\beta^{k-1}, \beta^*) = \min \left\{ \frac{p(X|\theta^k, \beta^*)p(\theta^k, \beta^*) \times g_\beta(\beta^*, \beta^{k-1})}{p(X|\theta^k, \beta^{k-1})p(\theta^k, \beta^{k-1}) \times g_\beta(\beta^{k-1}, \beta^*)}, 1 \right\} \quad (5)$$

otherwise set $\beta^k = \beta^{k-1}$

The resulting Markov chain has the desired stationary distribution $\pi(\theta, \beta) = p(\theta, \beta|X)$. It should be noted that if either g_θ or g_β is symmetric, then it cancels out in the probability of acceptance ratio. While it may be desirable to use a symmetric distribution to eliminate the proposal distribution, the chain will converge to the stationary distribution more quickly if asymmetric jumping rules are used [4].

Example

Patz and Junker [13] used the following proposal distributions for estimating parameters of the two-parameter logistic model:

$$\begin{aligned} g_B(\log(\beta_{1j}^{k-1}), \log(\beta_{1j})) &= N(\beta_{1j}^{k-1}, 0.3) \\ g_B(\beta_{2j}^{k-1}, \beta_{1j}) &= N(\beta_{2j}^{k-1}, 1.1) \end{aligned} \quad (6)$$

where β_{1j} is the a -parameter for item j , and β_{2j} is the b -parameter for item j .

The above algorithm provides a means to estimate both item parameters and person parameters jointly. However, in traditional estimation, MML has been favored over JML due to the consistency of the marginal estimates that is lacking in the joint

4 Markov Chain Monte Carlo IRT Estimation

estimates. Yao, Patz, and Hanson [20] developed an M–H within Gibbs algorithm that provides marginal estimates of the item parameters. Once the item parameter estimates are obtained, person parameters can be estimated using ML.

The marginal distribution of the parameters is given by:

$$P(\beta|X) \propto P(\beta) \int P(X|\theta, \beta) P(\theta) d\theta$$

This can be written as:

$$P(\beta) \prod_{i=1}^N \int_{\theta} \prod_{j=1}^J P(X_{ij}|\theta_i, \beta_j) P(\theta) d\theta$$

which can be approximated using quadrature points, resulting in:

$$P(\beta|X) \cong P(\beta) \prod_{i=1}^N h(\beta, X_i) \quad (7)$$

where

$$h(\beta, X_i) = \sum_{l=1}^n \prod_{j=1}^J P_{ij}(X_{ij}|\theta^l, \beta_j) A^l$$

where $\theta^1, \dots, \theta^n$ are quadrature points for the examinee population distribution, and $A^1, \dots, A^n$ are the weights at these points [20].

The algorithm used to draw samples from this marginal distribution of the item parameters is given below. Assuming that there are J items to be calibrated, the index j will refer to the item, whereas the index i will refer to one of the N examinees.

- (a) Draw $\beta_j^* \sim g_m(\beta_j|\beta_j^{m-1})$ where $g_m(\beta_j|\beta_j^{m-1})$ is a transition kernel from β_j to β_j^{m-1} .
- (b) For each item, J , calculate the acceptance probability of the parameters:

$$\alpha_j^*(\beta^{k-1}, \beta^*) = \min \left\{ \frac{P(\beta_j^*|\beta_{<j}^m, \beta_{>j}^{m-1}, X) \times g_m(\beta_j^{m-1}|\beta_j^*)}{P(\beta_j^{m-1}|\beta_{<j}^m, \beta_{>j}^{m-1}, X) \times g_m(\beta_j^*|\beta_j^{m-1})}, 1 \right\} \quad (8)$$

where

$$\begin{aligned} \beta_{<j}^m &= (\beta_i^m, i = 1, \dots, j-1) \\ \beta_{>j}^m &= (\beta_i^m, i = j+1, \dots, J) \end{aligned}$$

- (c) Accept each $\beta_j^m = \beta_j^*$ with probability α_j^* , otherwise let $\beta_j^m = \beta_j^{m-1}$

$$\alpha_j^*(\beta^{k-1}, \beta^*) = \min \left\{ \frac{P(\beta_j^*|\beta_{<j}^m, \beta_{>j}^{m-1}, X) \times g_m(\beta_j^{m-1}|\beta_j^*)}{P(\beta_j^{m-1}|\beta_{<j}^m, \beta_{>j}^{m-1}, X) \times g_m(\beta_j^*|\beta_j^{m-1})}, 1 \right\} \quad (9)$$

where

$$\begin{aligned} \beta_{<j}^m &= (\beta_i^m, i = 1, \dots, j-1) \\ \beta_{>j}^m &= (\beta_i^m, i = j+1, \dots, J) \end{aligned}$$

Example

There are many examples of using MCMC techniques to estimate parameters in IRT in the literature, as noted above. The example of Yao, Patz, and Hanson [20], where the marginal distribution was used, will be used here to illustrate the types of proposal distributions used for estimating parameters of the three-parameter logistic model. Since the 3PL is the model used, there are three-item parameters to be estimated for each item: a_j , b_j , and c_j . These parameters will be represented as elements of a parameter vector, β , and as such, the notation will be $a_j = \beta_{1j}$, $b_j = \beta_{2j}$, $c_j = \beta_{3j}$.

Proposal Distributions. Example proposal distributions for the three parameters are:

$$\begin{aligned} g_m(\beta_{1j}|\beta_{1j}^{m-1}) &\sim N(\beta_{1j}^{m-1}, 0.17^2) \\ g_m(\log(\beta_{2j})|\log(\beta_{2j}^{m-1})) &\sim N(\beta_{2j}^{m-1}, 0.17^2) \\ g_m(\beta_{3j}|\beta_{3j}^{m-1}) &= \begin{cases} 0.10 & \text{if } \beta_{3j} \in (\beta_{3j}^{m-1} - 0.05, \beta_{3j}^{m-1} + 0.05) \\ 0.00 & \text{otherwise} \end{cases} \end{aligned} \quad (10)$$

Convergence of the Markov Chain

The parameter estimates resulting from a Markov chain cannot be trusted unless there is evidence that the chain has converged to the posterior distribution. Cowles and Carlin [3] provide a description of several methods used to assess convergence, as well as software to implement the techniques. Another

approach is to create several different chains by choosing different starting values. If all the chains result in the same parameter estimates, evidence is provided that they have converged to the same distribution, and it must be the same distribution [5]. A common tool used to assess convergence is to use Geweke's [7] convergence diagnostic. The diagnostic is based on the equality of means of different parts of the Markov chains. Specifically, comparing the means from the first and last part of the chain, the two samples should have the same mean, if the draws came from the stationary distribution. A z-test is used to test the equality of means, where the asymptotic standard error of the difference is used as the standard error in the test statistic. Details are provided in [7].

Markov, Andrei Andreevich

Born: June 14, 1856, in Ryazan, Russia.

Died: July 20, 1922, in Petrograd (now St Petersburg), Russia.

Markov was a Russian mathematician who developed the theory of sequences of dependent random variables in order to extend the weak **law of large numbers** and **central limit theorem**. In the process, he introduced the concept of a chain of dependent variables, now known as a **Markov chains**. It is this idea that has been applied and developed in a number of areas of the behavioral sciences.

Markov's family moved to St Petersburg when he was a boy. At school, he did not excel in most subjects, with the exception of mathematics in which he showed precocious talent, developing what he believed to be a novel method for the solution of linear differential equations (it transpired that it was not new). On graduation, he entered the Faculty of Mechanics and Mathematics at St Petersburg University where he would stay for the remainder of his career. He defended his Ph.D. thesis in 1884 'On certain applications of the algebraic continuous fractions'. Markov was politically very active, for example, he opposed honorary membership of the Academy of Sciences for members of the royal family as he felt they had not earned the honor. His research was partially fueled by a similarly vehement dispute with Nekrasov who claimed that independence is required for the law of large numbers. Markov's study of what became known as Markov chains ultimately disproved Nekrasov's ideas. In 1913, Markov included in his book the first application of a Markov

chain. He studied the sequence of 20 000 letters in A. S. Pushkin's poem 'Eugeny Onegin' and established the probability of transitions between the vowels and consonants, which form a Markov chain. He died in 1922 as a result of sepsis that had developed after one of several operations that he underwent in the course of his life and that which stemmed from a congenital knee deformity and later complications.

A Markov chain consists of multiple states of a process and the probabilities of moving from one state to another over time, known as transition probabilities. A first-order Markov chain has the property that the subsequent state of the process is dependent on the current state but not on the preceding states. Higher-order Markov chains are dependent on previous states. The chief advantage that this method holds is the ability to analyze sequences of data. Markov chains have been used to model a wide range of behavioral data and cognitive processes, especially learning. Hidden Markov models are an extension in which the observable states are the product of unobservable states, which form a Markov chain. More recently, Markov chains have been used to generate sequences of data for use in Monte Carlo studies.

Markov Chains

Suppose you are playing blackjack. You are first dealt a '6' and then a '9', to give you a miserable total of 15. What are you going to do? If you choose to 'hit' (draw an additional card), your total will rise to

Total after drawing one additional card

p		12	13	14	15	16	17	18	19	20	21	>21

(1)

16, 17, 18, 19, 20 or 21, each with a probability of 1/13 (ignoring the complications of sampling without replacement), and with probability 7/13 you will 'go bust'. Those probabilities are independent of whether you received the '6' before the '9', or received the '9' first. They are independent of whether your 15 was made up of a '6' and a '9', or a '5' and a '10', or a '7' and an '8'. Your probabilities of future success depend solely on your present total, and owe nothing to how that total was reached. *That* is the *Markov* property.

The matrix above sets out the probabilities of different outcomes following a 'hit' with different totals (again ignoring the complications of sampling without replacement, and I emphasize that this is only a part of the probabilities associated with blackjack, but it will suffice for illustration). The future course of play depends only on the present total and this constitutes a *state* of the Markov chain. Each row of the matrix sums to unity and is therefore a proper multinomial distribution of outcomes, a different distribution for each state. If the total after one 'hit' still falls short of 21, it is possible to 'hit' again, and the transformation defined by the matrix can be

applied more than once. More generally, a matrix of this kind (with all rows summing to unity) can be used to calculate the possible evolution of many systems that similarly inhabit a set of discrete states. The essential condition for such calculation is that the entire future of the system depends only on its present state and is entirely independent of its past history.

Everyday examples of Markov systems tend to evolve in continuous time. The duration of telephone calls tends to an exponential distribution to a surprising degree of accuracy, and exhibits the Markov property. Suppose you telephone a call center to enquire about an insurance claim. 'Please hold; one of our consultants will be with you shortly.' About ten minutes later, still waiting for a 'consultant', you are losing patience. The unpalatable fact is that the time you must now *expect* to wait, after already waiting for ten minutes, is just as long as when you first started. The Markov property means that the future (how long you still have to wait) is entirely independent of the past (how long you have waited already). Light bulbs, on the other hand, are not Markov devices. The probability of failure as you switch the light on increases with the age of the bulb. Likewise, if the probabilities in (1) were recalculated on the basis of sampling *without* replacement, they would be found to depend on how the total had been reached – a '6' and a '9' versus a '5' and a '10' versus a '7' and an '8'.

The chief use of Markov chains in psychology has been in the formulation of models for learning. Bower [1] asked his subjects to learn a list of 10

2 Markov Chains

paired-associates. The stimuli were pairs of consonants and five were paired with the digit '1', five with '2'. Subjects were required to guess, if they did not know the correct response; after each response they were told the correct answer. Bower proposed the following model, comprised of two Markov states (L & U) and an initial distribution of pairs between them.

$$\begin{array}{c} \text{Trial } n \\ \begin{array}{c} L \\ U \end{array} \end{array} \begin{array}{c} \text{Trial } n+1 \\ \begin{array}{cc} L & U \end{array} \end{array} \begin{array}{c} \text{Probability} \\ \text{correct} \end{array} \begin{array}{c} \text{Initial} \\ \text{distribution} \end{array} \begin{array}{c} \left(\begin{array}{cc} 1 & 0 \\ c & 1-c \end{array} \right) \\ \frac{1}{2} \\ 0 \\ 1 \end{array} \quad (2)$$

$$\begin{array}{c} \text{Trial } n \\ \begin{array}{c} P \\ T \\ F \\ N \end{array} \end{array} \begin{array}{c} \text{Trial } n+1 \\ \begin{array}{ccc} P & T & F \end{array} \end{array} \begin{array}{c} \text{Probability} \\ \text{of} \\ \text{avoidance} \end{array} \begin{array}{c} \text{Initial} \\ \text{distribution} \end{array} \begin{array}{c} \left(\begin{array}{ccc} 1 & 0 & 0 \\ 0 & (1-q) & q \\ e & (1-e)(1-q) & (1-e)q \\ cd & c(1-d)(1-q) & c(1-d)q \end{array} \right) \\ 0 \\ 0 \\ 0 \\ (1-c) \end{array} \begin{array}{c} 1 \\ 1 \\ 0 \\ 0 \end{array} \begin{array}{c} 0 \\ 0 \\ 0 \\ 1 \end{array} \quad (4)$$

This model supposes that on each trial each hitherto unlearned pairing is learnt with probability c and, until a pairing is learnt, the subject is guessing (correct with probability $1/2$). Once a pairing is learnt (state L), subsequent responses are always correct. There is no exit from state L , which is therefore *absorbing*. State U (unlearned), on the other hand, is *transient*. (More precisely, a state is said to be transient if return to that state is less than certain.) Bower's data fitted his model like a glove: but it also needs to be said that any more complicated experiment poses problems not seen here.

This is not the only way that Bower's idea can be formulated. The three-state model

$$\begin{array}{c} \text{Trial } n \\ \begin{array}{c} A \\ C \\ E \end{array} \end{array} \begin{array}{c} \text{Trial } n+1 \\ \begin{array}{cc} C & E \end{array} \end{array} \begin{array}{c} \text{Probability} \\ \text{correct} \end{array} \begin{array}{c} \text{Initial} \\ \text{distribution} \end{array} \begin{array}{c} \left(\begin{array}{cc} 1 & 0 \\ 0 & \frac{1}{2} \end{array} \right) \\ \frac{1}{2}(1-d) \\ \frac{1}{2} \end{array} \begin{array}{c} 1 \\ 1 \\ 0 \end{array} \begin{array}{c} \frac{1}{2}d \\ \frac{1}{2}(1-d) \\ \frac{1}{2} \end{array} \quad (3)$$

with $d = 2c/(1+c)$ is equivalent to the previous two-state model (2), in the sense that the probability of any and every particular set of data is the same

whichever model is used for the calculation [4, pp. 312–314]. The data for each paired-associate in Bower's experiment consists of a sequence of guesses followed by a criterion sequence of correct responses. The errors all occur in State E , correct guesses prior to the last error in State C , and all the responses following learning (plus, possibly some correct guesses immediately prior to learning), in State A . These three states are all *identifiable*, in the sense that (provided there is a sufficiently long terminal sequence of correct responses to allow the inference that the pair has been learned) it can be inferred uniquely from the sequence of responses which state the system occupied at any given trial in the sequence. Models (2) and (3) are *equivalent*.

A more elaborate model of this kind was proposed by Theios and Brelsford [6] to describe avoidance learning by rats. The rats start off naïve (State N) and are shocked. At that point, they learn how to escape with probability c and exit State N . They also learn, for sure, the connection between the warning signal (90 dB noise) and the ensuing shock, but that connection is formed only temporarily with probability $(1-d)$ (i.e., exit to States T or F) and may be forgotten with probability q (State F , rather than T) before the next trial. A trial in State F (meaning of warning signal forgotten) means that the rat will be shocked, whence the connection of the warning signal to the following shock may be acquired permanently with probability e . Here again all the states are identifiable from the observed sequence of responses. The accuracy of the model was well demonstrated in a series of experimental manipulations by Brelsford [2].

A rather different use of a Markov chain is illustrated by **Shannon's** [5] approximations to English text. English text consists of strings of letters and spaces (ignoring the punctuation) conforming to various high-level sequential constraints. Shannon approximated those constraints to varying degrees

with a Markov chain. A *zeroth* order approximation was produced by selecting succeeding characters independently and at random, each with probability $1/27$. A first-order approximation consisted of a similar sequence of letters, but now selected in proportion to their frequencies of occurrence in English text. A second-order approximation was constructed by matching successive pairs of letters to their natural frequency of occurrence. In this approximation, not only did the overall letter frequencies match English text, but the probabilities of selection depended also on the letter preceding. A third order approximation

IN NO IST LAT WHEY CRATICT FROURE BIRS
GROCID PONDEOME OF DEMONSTURES OF
THE REPTAGIN IS REGOACTIONA OF CRE.

meant that each sequence of three successive letters was matched in frequency to its occurrence in English text. The corresponding Markov chain now has 27^2 distinct states. There was, however, no need to construct the transition matrix (a hideous task); it was sufficient to take the last two letters of the approximation and open a book at random, reading on until those same two letters were discovered in correct sequence. The approximation continued with whatever letter followed the two in the book.

The 27×27 matrix for constructing a second-order approximation illustrates some further properties of Markov chains. Since all 27 characters will recur, sooner or later, in English text, all states of the chain (the letters A to Z and the space) can be reached from all other states. The chain is said to be *irreducible*. In comparison, in example (4), return to State N is not possible after it has been left and thereafter the chain can be reduced to just three states. If a Markov chain is irreducible, it follows that all states are certain to recur in due course. A *periodic* state is one that can be entered only every n steps, after which the process moves on to the other states. States that are not subject to such a restriction are *aperiodic*, and if return is also certain, they are called *ergodic*. Since the 27×27 matrix in question is irreducible, all its states are ergodic. It follows that, however the approximation to English text starts off, after a sufficient length has been generated, the frequency of different states (letters and spaces) will tend to a stationary distribution, which, in this case, will correspond to the long-run frequency of the characters in English text.

To sum-up, the matrix (5) exemplifies several important features of Markov chains. The asterisks denote any arbitrary entry between 0 and 1; the row sums, of course, are all unity.

$$\begin{array}{c}
 S_1 \quad S_2 \quad S_3 \quad S_4 \quad S_5 \quad S_6 \quad S_7 \quad S_8 \quad S_9 \\
 \begin{array}{c}
 S_1 \\
 S_2 \\
 S_3 \\
 S_4 \\
 S_5 \\
 S_6 \\
 S_7 \\
 S_8 \\
 S_9
 \end{array}
 \begin{pmatrix}
 * & * & * & * & * & * & * & * & * \\
 * & * & * & * & * & * & * & * & * \\
 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\
 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\
 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\
 0 & 0 & & 1 & 0 & 0 & 0 & 0 & 0 \\
 0 & 0 & 0 & 0 & 0 & 0 & * & * & * \\

 0 & 0 & 0 & 0 & 0 & 0 & * & * & *
 \end{pmatrix}
 \end{array}
 \quad (5)$$

1. It is possible to access all other states from S_1 and S_2 , but return (except from S_1 to S_2 and vice-versa) is not possible. S_1 and S_2 are *transient*.
2. Once S_3 is entered, there is no exit. S_3 is *absorbing*.
3. S_4 , S_5 , and S_6 exit only to each other. They form a closed (absorbing) subset; the subchain comprised of these three states is irreducible. Moreover, once this set is entered, S_4 exits only to S_5 , S_5 only to S_6 , and S_6 only to S_4 , so that thereafter each of these states is visited every three steps. These states are *periodic*, with period 3.
4. S_7 , S_8 , and S_9 likewise exit only to each other, and also form a closed irreducible subchain. But each of these three states can exit to each of the other two and the subchain is *aperiodic*. Since return to each of these three states is certain, once the subset has been entered, the subchain is *ergodic*.

For further properties of Markov chains the reader should consult [3, Chs. XV & XVI].

Martingales

A simple example of a martingale would be one's cumulative winnings in an 'absolutely fair' game. For example, Edith and William play a regular game of bridge, once a week, against Norman and Sarah for £10 per 100 points. This is a very satisfactory arrangement because these two pairs are exactly matched in their card skills. Coupled with a truly random assignment of cards to the four players, this match ensures that their *expected* winnings on each hand are zero; the game is *absolutely fair*. This does not, however, preclude one pair or the other building up a useful profit over the course of time.

Norman and Sarah's cumulative winnings are

$$S_n = X_1 + X_2 + \cdots + X_n, \quad (1)$$

where X_i is the amount they won on the i th hand. This equation describes an additive process, and there are two elementary conditions on the X_i that permit simple and powerful inferences about the behavior of the sums S_n .

1. If the X_n are independent and identically distributed, (1) describes a **random walk** *qv*. In a random walk, successive steps, X_n , are independent; this means that the distributions of successive S_n can be calculated by repeated convolution of the X_n .
2. If, instead, the expectations of successive X_n are zero, the sequence $\{S_n\}$ is a *martingale*. I emphasize that X_n need not be independent of the preceding steps $\{X_i, i = 1, \dots, n-1\}$, merely that its expectation is always zero, irrespective of the values that those preceding steps happen to have had. Formally, $E\{X_{n+1}|X_1, X_2, \dots, X_n\} = 0$. This has the consequence that $E\{S_{n+1}|X_1, X_2, \dots, X_n\} = S_n$ (which is the usual definition of a martingale).

Continuing the preceding example, the most important rewards in bridge come from making 'game', that is, 100 points or more from contracts bid and made. If Norman and Sarah already have a part-score toward 'game' from a previous hand, their bidding strategy will be different in consequence. Once a partnership has made 'game', most of their penalties (for failing to make a contract) are doubled; so bidding strategy changes again. None of

these relationships abrogate the martingale property; the concept is broad.

The martingale property means that the variances of the sums S_n are monotonically increasing, whatever the relationship of X_{n+1} to the preceding X_n . The variance of S_{n+1} is

$$\begin{aligned} E\{(S_n + X_{n+1})^2\} &= E\{S_n^2 + 2S_n X_{n+1} + X_{n+1}^2\} \\ &= E\{S_n^2 + X_{n+1}^2\}, \end{aligned} \quad (2)$$

because $E\{X_{n+1}\} = 0$. From this, it follows that if the variances of the sums S_n are bounded, then S_n tends to a limiting distribution [2, p. 236]. Martingales are important, not so much as models of behavior in their own right, but as a concept that simplifies the analysis of more complicated models, as the following example illustrates.

Yellott [9] reported a long binary prediction experiment in which observers had to guess which of two lights, A and B, would light up on the next trial. A fundamental question was whether observers modified their patterns of guessing on every trial or only when they found they had guessed wrongly. The first possibility may be represented by a linear model. Let p_n be the probability of choosing light A on trial n . If Light A does indeed light up, put

$$p_{n+1} = \alpha p_n + (1 - \alpha); \quad (3a)$$

otherwise

$$p_{n+1} = \alpha p_n. \quad (3b)$$

Following each trial p_n in (3) is replaced by a weighted average of p_n and the light actually observed (counting Light A as 1 and Light B as 0). If Light A comes on with probability a , fixed over successive trials, then p_n tends asymptotically to a – that is, 'probability matching', a result that is commonly observed in binary prediction. This finding provides important motivation for the linear model, except that the same result can be derived from other models [1, esp. pp. 179–181]. So, for the last 50 trials of his experiment, Yellott switched on whichever light the subject selected (i.e., noncontingent success reinforcement with probability 1). If observers modified their patterns of guessing only when they had guessed wrong, noncontingent success reinforcement should effect no change at all in the pattern of guessing. But for the linear model on

2 Martingales

trial $n + 1$,

$$\begin{aligned} E\{p_{n+1}\} &= p_n[\alpha p_n + (1 - \alpha)] + (1 - p_n)[\alpha p_n] \\ &= p_n, \end{aligned} \quad (4)$$

so the sequence $\{p_n\}$ is a martingale. The variance of p_n therefore increases monotonically and, for any one sequence of trials, p_n should tend either to 0 or to 1. Yellott found no systematic changes of that kind.

However, a formally similar experiment by Howarth and Bulmer [4] yielded a different result. The observers in this experiment were asked to report a faint flash of light that had been adjusted to permit about 50% detections. The intensity of the light was constant over successive trials, but there was no knowledge of results. So the response, detection or failure to detect, fulfilled a role analogous to noncontingent success reinforcement. Successive responses were statistically related in a manner consistent with the linear model (3). Moreover, the authors reported ‘The experiment was stopped on two occasions after the probability of seeing had dropped almost to zero’ [4, p. 164]; that is, for two observers, p_n decreased to 0. There was a similar decrease to zero in the proportion of positive diagnoses by a consultant pathologist engaged in screening cervical smears [3]. Her frame of judgment shifted to the point that she was passing as ‘OK’ virtually every smear presented to her for expert examination.

The tasks of predicting the onset of one of two lights or of detecting faint flashes of light do not make sense unless both alternative responses are appropriate on different trials. This generates a prior expectation that some particular proportion of each kind of response will be required. A prior expectation can be incorporated into the linear model by replacing the reinforcement in (3) (Light A = 1, Light B = 0) with the response actually uttered (there was no reinforcement in Howarth and Bulmer’s experiment) and then replacing the response (1 for a detection, 0 for a miss) with a weighted average of the prior expectation and the response. This gives

$$p_{n+1} = \alpha p_n + (1 - \alpha)[b\pi_\infty + (1 - b)]; \quad (5a)$$

$$p_{n+1} = \alpha p_n + (1 - \alpha)b\pi_\infty. \quad (5b)$$

Here, π_∞ is the prior expectation of what proportion of trials will present a flash of light for detection,

and the expression in square brackets applies the linear model of (3) to the effect of that prior expectation. The probability of detection tends asymptotically to π_∞ . But, notwithstanding that the mean no longer satisfies the martingale condition, the variance still increases to a limiting value, greater than would be obtained from independent binomial trials [5, p. 464]. This increased variability shows up in the proportions of positive smears reported by different pathologists [6], in the proportions of decisions (prescription, laboratory investigation, referral to consultant, follow-up appointment) by family doctors [8, p. 158] and in the precision of the ‘quantal’ experiment. The ‘quantal’ experiment was a procedure introduced by Stevens and Volkman [7] for measuring detection thresholds. Increments of a fixed magnitude were presented repeatedly for 25 successive trials. The detection probability for that magnitude was estimated by the proportion of those increments reported by the observer. The precision of 25 successive observations in the ‘quantal’ experiment is equivalent to about five independent binomial trials [5] (*see Catalogue of Probability Density Functions*).

Matching

Models for Matched Pairs

Evaluation is generally inherently comparative. For example, a treatment is generally neither ‘good’ nor ‘bad’ in absolute terms, but rather better than or worse than another treatment at bringing about the desired result or outcome. The studies that allow for such comparative evaluations must then also be comparative. It would not do, for example, to study only one treatment and then declare it to be the winner. To isolate the effects of the treatments under study, avoid **confounding** treatment effects with unit effects, and possibly increase the **power** of the study to detect treatment differences, the units under study must be carefully matched across treatment groups. To appreciate the need to control such confounding, consider comparing the survival times of patients in a cancer clinic to those of patients in a sports injury clinic. It might be expected that the patients with sports injuries would live longer, but this is not generally accepted as proof that treatment (for either sports injuries or for cancer) is better at a sports injury clinic than it is at a cancer center. The difference in survival times across the ‘treatment’ groups is attributable not to the treatments themselves (cancer center vs. sports injury clinic) but rather to underlying differences in the patients who choose one or the other.

While the aforementioned example is an obvious example of confounding, and one that is not very likely to lead to confusion, there are less obvious instances of confounding that can lead to false conclusions. For example, Marcus [6] evaluated a randomized study of a culturally sensitive AIDS education program [13]. At baseline, the treatment group had significantly lower AIDS knowledge scores (39.89 vs. 36.72 on a 52-question test, $p = 0.005$), so an unadjusted comparison would be confounded.

The key to avoiding confounding is in ensuring the comparability of the comparison groups in every way other than the treatments under study. This way, by the process of elimination, any observed difference can be attributed to differences in the effects of the treatments under study. Ideally, the control group for any given patient or set of patients would be the same patient or set of patients, under identical conditions. This is the idea behind **crossover trials**,

in which patients are randomized not to treatment conditions, but rather to sequences of treatment conditions, so that each patient experiences each treatment condition, in some order.

But crossovers are not the ideal solution, because while each patient is exposed to each treatment condition, this exposure is not under identical conditions. Time must necessarily elapse between the sequential exposures, and patients do not remain the same over time, even if left untreated. The irony is that the very nature of the crossover design, in which the patient is treated initially with one treatment in the hope of improving some condition (i.e., changing the patient), interferes with homogeneity over time. Under some conditions, **carryover effects** (the effect of treatment during one period on outcomes measured during a subsequent period when a different treatment is being administered) may be minimal, but, in general, this is a serious concern.

Besides crossover designs, there are other methods to ensure matching. The matching of the comparison groups may be at the group level, at the individual unit level, or sometimes at an intermediate level. For example, if unrestricted randomization is used to create the comparison groups, then the hope is that the groups are comparable with respect to both observed and unobserved covariates, but there is no such hope for any particular subset of the comparison groups. If, however, the randomization is stratified, say by gender, then the hope is that the females in one treatment group will be comparable to the females in each other treatment group, and that the males in one treatment group will be comparable to the males in each other treatment group (*see Stratification*). When **randomization** is impractical or impossible, the matching may be undertaken in manual mode. There are three types of matching – simple matching, symmetrical matching, and split sample [5]. In simple matching, a given set of covariates, such as age, gender, and residential zip code, may be specified, and each unit (subject) may be matched to one (resulting in paired data) or several other subjects on the basis of these covariates. In most situations, simple matching is also done to increase the power of the study to detect differences between the treatment groups due to the reduction in the variability between the treatment groups. Pauling [8] presented a data set of simple matching in his Table 33.2. This table presents the time until cancer patients were determined to be beyond treatment.

2 Matching

There are 11 cancer patients who were treated with ascorbic acid (vitamin C), and ‘for each treated patient, 10 controls were found of the same sex, within five years of the same age, and who had suffered from cancer of the same primary organ and histological tumor type. These 1000 cancer patients (overall there were more than 11 cases, but only these 11 cases are presented in Table 33.2) comprise the control group. The controls received the same treatment as the ascorbic-treated patients except for the ascorbate’ [8]. Of note, Pauling [8] went on to state that ‘It is believed that the ascorbate-treated patients represent a random selection of all of the terminal patients in the hospital, even though no formal randomization process was used’ [8]. It would seem that what is meant here is that there are no systematic differences to distinguish the cases from the controls, and this may be true, but it does not, in any way, equate to proper randomization [1].

The matching, though not constituting randomization, may provide somewhat of a basis for inference, because if the matching were without any hidden bias, then the time to ‘untreatability’ for the case would have the same chance to exceed or to be exceeded by that of any of the controls matched to that case. Under this assumption, one may proceed with an analysis based on the ranking of the case among its controls. For example, Case #28 had a time of 113 days, which is larger than that of five controls and smaller than that of the other five controls. So, Case #28 is quite typical of its matched controls. Of course, any inference would be based on all 11 cases, and not just Case #11.

There is **missing data** for one of the controls for Case #35, so we exclude this case for ease of illustration (a better analysis, albeit a more complicated one, would make use of all cases, including this one), and proceed with the remaining 10 cases, as in Table 1. Cases #37 and #99 had times of 0 days, and each had at least one control with the same time, giving rise to the ties in Table 1. These ties also complicate the analysis somewhat, but for our purposes, it will not matter if they are resolved so that the case had the longer time or the shorter time, as the ultimate conclusion will be that there was no significant difference at the 0.05 level. To illustrate this, we take a conservative approach (actually, it is a liberal approach, as it enhances the differences between the groups, but this is conservative relative to the claim that there is no significant difference) as follows. First, we note that

Table 1 Data from Pauling [8]

Case	Controls with shorter times	Ties	Controls with longer times
28	5	0	5
33	1	0	9
34	6	0	4
36	9	0	1
37	0	2	8
38	2	0	8
84	6	0	4
90	4	0	6
92	2	0	8
99	0	1	9
Sum	35	3	62

there were 62 shorter case times versus only 35 longer case times (this could form the basis for a U-test [10, 11], ignoring the ties), and so the best chance to find a difference would be with a one-sided test to detect shorter case times. We then help this hypothesis along by resolving the ties so that the case times are always shorter. This results in combining the last two columns of Table 1, so that it is 35 versus 65.

As noted, the totals, be it 35 versus 62 or 35 versus 65, are sufficient to enable us to conduct a U-test (*see Wilcoxon–Mann–Whitney Test*) [10, 11]. However, we propose a different analysis because the U-test treats as interchangeable all comparisons; we would like to make more use of the matched sets. Consider, then, any given rank out of the 11 (one case matched to 10 controls). For example, consider the second largest. Under the null hypothesis, the probability of being at this rank or higher is 2/11, so this can form the basis for a binomial test. Of course, one can conduct a binomial test for any of the rank positions. The data summary that supports such analyses is presented in Table 2. The rank of the case is one more than the number of control times exceeded by the case time, or one more than the second column of Table 1. It is known that artificially small P values result from selection of the test based upon the data at hand, in particular, when dealing with maximized differences among cut-points of an ordered contingency table, or a Lancaster decomposition (*see Kolmogorov–Smirnov Tests*) [2, 9]. Nevertheless, we select the binomial test that yields the most significant (smallest) one-sided P value, which is at rank 7.

We see that 9 of the 10 cases had a rank less than seven. The point probability of this outcome is, by

Table 2 Data from Table 1 put into a form amenable for binomial analysis

Rank	Sets in which the case has this rank	Cumulative
1	2 ^a	2
2	1	3
3	2	5
4	0	5
5	1	6
6	1	7
7	2	9
8	0	9
9	0	9
10	1	10
11	0	10
Total	10	

^aCases #37 and #99 have the lowest rank by the tie-breaking convention.

the binomial formula, $(10)(7/11)^9(4/11) = 0.0622$. The P value is this plus the null probability of all other more extreme outcomes. In this case, the only more extreme outcome is to have all 10 cases have rank less than seven, and this has null probability $(7/11)^{10} = 0.0109$, so the one-sided binomial P value is the sum of these two null probabilities, or 0.0731, which, with every advantage given toward a finding of statistical significance, still came up short. This is not surprising with so small a sample size. The method, of course, can be applied with larger sample sizes as well.

The second type of matching is symmetrical matching, where the effect of two different treatments are tested on opposite sides of the body. Kohnen et al. [4] compared the difference between standard and a modified (zero-compression) Hansatome micro-keratome head in the incidence of epithelial defects. Ninety-three patients (186 eyes) were enrolled in the study. To avoid confounding, each patient's two eyes were matched. In one eye, the flaps were created using the standard Hansatome head and in the other eye, the flaps were created using a modified design (zero-compression head). Epithelial defects occurred in 21 eyes in which the standard head was used and in 2 eyes (2.1%) in which the zero-compression head was used. Two patients who had an epithelial defect using the zero-compression head also had an epithelial defect in the eye in which the standard head was used. McNemar's test is appropriate to analyze such data from matched pairs of subjects

with a dichotomous (yes–no) response. The P value based on McNemar's test [7] is less than 0.001, and suggests that the modified Hansatome head significantly reduced the occurrence of the epithelial defects. To compare matched pairs with continuous response, the paired t Test [12] or Wilcoxon signed-ranks test [3] is proper. Shea et al. [14] studied the microarchitectural bone adaptations of the concave and convex spinal facets in idiopathic scoliosis. Biopsy specimens of facet pairs at matched anatomic levels were obtained from eight patients. The concave and convex facets were analyzed for bone porosity. The mean porosity (and standard deviation) for the concave and convex facets was 16.5% $\pm$ 5.8% and 24.1% $\pm$ 6.2%, respectively. The P value based on the paired t Test is less than 0.03, and suggests that the facets on the convex side were significantly more porous than those on the concave side.

The third type of matching is the split sample design, in which each individual is divided into two parts and one treatment is randomized to one part, while the other part gets the second treatment. For example, a piece of fabric could be cut into two pieces and each piece is tested with one of two detergents. Symmetrical matching and split samples both result in paired data. With these designs, the study usually has more power to detect differences between the treatment groups, compared to unmatched designs, because the individual variation is reduced.

Matching bears some resemblance to randomized trials that stratify by time of entry onto the trial, as cohorts of patients form blocks, and randomization occurs within the block. Often, each block will have the same number of cases (called *treated patients*) and controls (patients treated with the control group), with obvious modification for more than two treatment groups. The similarity in the previous sentence applies both within blocks and across blocks; that is, often any given block has the same number of patients randomized to each treatment condition (1:1 allocation within each block), and the size of each block will be the same (constant block size). To the extent that time trends render patients within a block more comparable to each other than to patients in other blocks, we have a structure similar to that of the Pauling [8] matched study, except that each matched set, or block, may have more than one case, or treated patient.

Mathematical Psychology

Mathematical psychology deals with the use of mathematical and computational modeling methods to measure and explain psychological processes. Although probabilistic models dominate the work in this area, mathematical psychology is distinctly different from the statistical analysis of data. While there is a strong interest in mathematical psychology with the measurement of psychological processes, mathematical psychology does not deal with multiple-item tests such as intelligence tests. The study of multi-item tests and questionnaires is a central focus of psychometrics (see **History of Psychometrics; Psychophysical Scaling**). Psychometrics has a close linkage with education and clinical psychology—fields concerned with psychological assessment. In contradistinction to psychometrics, mathematical psychology is concerned with measuring and describing the behavioral patterns demonstrated in experimental research. Thus, mathematical psychology has a close tie to experimental psychology—a linkage that is analogous to the connection between theoretical and experimental physics.

The Development of Mathematical Psychology

One of the earliest examples of experimental psychology is an 1860 book by **Fechner** [10] on psychophysics – the science of relating physical dimensions to perceived psychological dimensions. This treatise is also a pioneering example of mathematical psychology. While Fechner's work was followed by a steady stream of experimental research, there was not a corresponding development for mathematical psychology. Mathematical psychology was virtually nonexistent until after World War II. By that time psychological science had progressed to the point where (a) statistical tools for data analysis were common, (b) rich databases were developed in most areas of psychology that demonstrated regular behavioral patterns, and (c) a wide range of theories had been proposed that were largely verbal descriptions. During World War II, a number of psychologists worked with engineers, physicists, and mathematicians. This collaboration stimulated

the development of a more rigorous theoretical psychology that employed mathematical methods. That time period also saw the rapid development of new branches of applied mathematics such as control theory, cybernetics, information theory, system theory, game theory, and automata theory. These new mathematical developments would all prove useful in the modeling of psychological processes.

By the 1950s, a number of papers with mathematical models were being published regularly in the journal, *Psychological Review*. Books and monographs about mathematical psychology also began appearing [22]. Regular summer workshops on mathematical behavioral sciences were being conducted at Stanford University. Early in the 1960s, there was an explosion of edited books with high quality papers on mathematical psychology. Eventually, textbooks about mathematical psychology were published [7, 14, 15, 27, 33]. These texts helped to introduce the subject of mathematical psychology into the graduate training programs at a number of universities. In 1964, the *Journal of Mathematical Psychology* was launched with an editorial board of Richard Atkinson, **Robert Bush**, **Clyde Coombs**, William Estes, Duncan Luce, William McGill, George Miller, and Patrick Suppes. The first conference on mathematical psychology was held in 1968. The next eight meetings were informally organized by the interested parties, but in 1976, an official professional society was created – the Society for Mathematical Psychology. The officers of this organization (a) decide the location and support the arrangements for an annual conference, (b) select the editor and recommend policies for the *Journal of Mathematical Psychology*, (c) recognize new researchers in the field by offering a 'young investigator' award, and (d) recognize especially important new work by awarding an 'outstanding paper' prize.

Outside North America, the subfield of mathematical psychology developed as well. In 1965, the *British Journal of Statistical Psychology* changed its name to the *British Journal of Mathematical and Statistical Psychology* in order to include mathematical psychology papers along with the more traditional test theory and psychometric papers. In 1967, the journal *Mathematical Social Sciences* was created with an editorial board containing many European social scientists as well as North Americans. In 1971, a group of European mathematical psychologists held a conference

in Paris. The group has come to be called the *European Mathematical Psychology Group*. This society also has an annual meeting. A number of edited books have emerged from the papers presented at this conference series. In 1989, Australian and Asian mathematical psychologists created their own series of research meetings (i.e., the Australasian Mathematical Psychology Conference).

Research in Mathematical Psychology

Mathematical psychology has come to be a broad topic reflecting the utilization of mathematical models in any area of psychology. Because of this breadth, it has not been possible to capture the content of mathematical psychology with any single volume. Consequently, mathematical psychology research is perhaps best explained with selected examples. The following examples were chosen to reflect a range of modeling techniques and research areas.

Signal Detection Theory

Signal detection theory (SDT) is a well-known model that has become a standard tool used by experimental psychologist. Excellent sources of information about this approach can be found in [11, 34]. The initial problem that motivated the development of SDT was the measurement of the strength of a sensory stimulus and the control of decision biases that affect detection processes. On each trial of a typical experiment, the subject is presented with either a faint stimulus or no stimulus. If the subject adopts a lenient standard for claiming that the stimulus is present, then the subject is likely to be correct when the stimulus is present. However, such a lenient standard for decision making means that the subject is also likely to have many false alarms, that is, claiming a stimulus is present when it is absent. Conversely, if a subject adopts a strict standard for a detection decision, then there will be few false alarms, but at the cost of failing on many occasions to detect the stimulus. Although SDT developed in the context of sensory psychophysics, the model has also been extensively used in memory and information processing research because the procedure of providing either stimulus-present or stimulus-absent trials is common in many research areas.

In what might be called the *standard form of SDT*, it is assumed that there are two underlying normal distributions on a psychological strength axis. One distribution represents the case when the stimulus is absent, and the other distribution is for the case when the stimulus is present. The stimulus-present distribution is shifted to the right on the strength axis relative to the stimulus-absence distribution. Given data from at least two experimental conditions where different decision criteria are used, it is possible to estimate the parameter d' , which is defined as the separation between the two normal distributions divided by the standard deviation of the stimulus-absent distribution. It is also possible to estimate the ratio of the standard deviations of the two distributions.

Multinomial Process Tree Models

The data collected in a signal detection experiment are usually categorical, that is, the hit rates and false alarm rates under conditions that have different decision criteria. In fact, many other experimental tasks also consist of measuring proportions in various response categories. A number of mathematical psychologists prefer to model these proportions directly in terms of underlying psychological processes. The categorical information is referred to as multinomial data. In this area of research, the mathematical psychologist generates a detailed probability description as to how underlying psychological processes result in the various proportions for the observed multinomial data. Most researchers develop a probability tree representation where the branches of the tree correspond to the probabilities of the latent psychological processes. The leaves of the tree are the observed categories in an experiment. These models have thus come to be called *multinomial processing tree (MPT)* models.

An extensive review of many of MPT models in psychological research can be found in [3]. Given experimental data, that is, observed proportions for the various categories for responding, the latent psychological parameters of interest can be estimated. General methods for estimating parameters for this class of models are specified in [5, 12]. The goal of MPT modeling is to obtain measures of the latent psychological parameters. For example, a method was developed to use MPT models to obtain separate

measures of memory storage and retrieval for a task that has an initial free recall test that is followed by a series of forced-choice recognition tests [5, 6]. MPT models are tightly linked to a specific experimental task. The mathematical psychologist often must invent an experimental task that provides a means of measuring the underlying psychological processes of interest.

Information Process and Reaction Time Models

A number of mathematical psychologists model processes in the areas of psychophysics, information processing (*see* **Information Theory**), and cognition; see [9, 16, 19, 30]. These researchers have typically been interested in explaining properties of dependent measures from experiments, such as the participants' response time, percentage correct, or the trade-off of time with task accuracy. For example, many experiments require the person to make a choice response, that is, the individual must decide if a stimulus is the same or different from some standard. The statistical properties of the time distribution of 'same' response are not equivalent to the distribution of the 'different' response. Mathematical psychologists have been interested in accounting for the entire response-time distribution for each type of response. One successful model for response time is the relative judgment, **random walk model**, [17]. Random walk models are represented by a state variable (a real-value number that reflects the current state of evidence accumulation). The state variable is contained between two fixed boundaries. The state variable for the next time increment is the same as the prior value plus or minus a random step amount. Eventually, the random walk of the state variable terminates when the variable reaches either one of the two boundaries. The random walk model results in a host of predictions for the same-different response times.

Axiomatic Measurement Theories and Functional Equations

Research in this area does not deal with specific stochastic models of psychological processes but rather focuses on the necessary and sufficient conditions for a general type of measurement scale or a form of a functional relationship among variables.

Typically, a minimal set of principles or axioms is considered, and the consequences of the assumed axioms are derived. If the resulting theory is not supported empirically, then at least one of the axioms must be in error. Furthermore, this approach provides experimental psychologists with an opportunity to test the theory by assessing the validity of essential axioms.

A well-known example of the axiomatic approach is the choice axiom [18]. To illustrate the axiom, let us consider an example of establishing a preference ordering of a set of candidates. For each pair of candidates, there will be choice probability P_{ij} that denotes the probability that candidate i is preferred over candidate j . The choice axiom states that the probability that any candidate is preferred is statistically independent of the removal of one of the candidates. In essence, this principle is the same as a long-held principle in voting theory called the *independence* of irrelevant alternatives, that is, the relative strength between two candidates should not change if another candidate is disqualified. Luce shows that this axiom implies that there must exist numbers v_i associated with each alternative, and that the choice probability is $v_i/(v_i + v_j)$. The result of this formal analysis also establishes that we cannot characterize the choice probabilities in terms of a ratio of underlying strengths if we can show empirically that for some pair of candidates the relative preference is altered by the removal of some other candidate.

A similar approach to research in mathematical psychology can be found in the utilization of functional equation theory. D'Alembert, an eighteenth century mathematician, initiated this branch of mathematics, and it has proved to be important for psychological theorizing. Perhaps the most famous illustration of functional equation analysis from mathematics is the Cauchy equation. It can be proved that the only continuous function that satisfies the constraint that $f(x + y) = f(x) + f(y)$ where x and y are nonnegative is $f(x) = cx$, where c is a constant. Functional equation analysis can be used to determine the form of a mathematical relationship between critical variables. Theorems are developed that demonstrate that only one mathematical function satisfies a given set of requirements without the necessity of curve fitting or statistical analysis. To illustrate this approach, let us consider the analysis provided by Luce [20] in the

area of psychophysics. Consider two stimuli of intensities I and I' , respectively, and let $f(I)$ and $f(I')$ be the corresponding psychological perception of the stimuli. It can be established that if $I/I' = c$, where c is a constant, and if $f(I)/f(I') = g(c)$, then $f(I)$ must be a power function, that is, $f(I) = AI^\beta$, where A and β are positive constants that are independent of I .

Judgment and Decision-making Models

Economics and mathematics have developed rational models for decision making. However, there is considerable evidence from experimental psychology that people often do not behave according to these 'normative' rational models [13]. For example, let us consider the psychological worth of a gamble. Normative economic theory posits that a risky commodity (e.g., a gamble) is worth the expected utility of the gamble. Utility theory was first formulated by the mathematician Daniel **Bernoulli** in 1738 as a solution to a gambling paradox. Prior to that time, the worth of a gamble was the expected value for the gamble, for example, given a gamble that has a 0.7 probability for a gain of \$10 and a probability of 0.3 for a loss of \$10, the expected value is $0.7(\$10) + (0.3)(-\$10) = \$4$. However, Bernoulli considered a complex gamble based on a bet doubling system and showed that the gamble had infinite expected value. Yet, individuals did not perceive that gamble as having infinite value. To resolve this discrepancy, Bernoulli replaced the monetary values with subjective worth numbers for the monetary outcomes – these numbers were called *utility values*. Thus, for the above example, the subjective utility is $0.7[U(\$10)] + (0.3)[U(-\$10)]$, where the u function is nonlinear, monotonic increasing function of dollar value. General axioms for expected **utility theory** have been developed [31], and that framework has become a central theoretical perspective in economics. However, experimental psychologists provided numerous demonstrations that this theory is not an accurate descriptive theory. For example, the Allais paradox illustrates a problem with expected utility theory [7, 32]. Subjects greatly prefer a certain \$2400 to a gamble where there is a 0.33 probability for \$2500, a 0.66 probability for \$2400, and a 0.01 chance for \$0. Thus, from expected utility theory, it follows that $U(\$2400) > 0.33[U(\$2500)] +$

$0.66[U(\$2400)] + 0.01[U(\$0)]$, which is equivalent to $0.34[U(\$2400)] > 0.33[U(\$2500)] + 0.01[U(\$0)]$. However, these same subjects prefer a lottery with a 0.33 chance for \$2500 to a lottery that has a 0.34 chance for \$2400. This second preference implies according to expected utility theory that $0.33[U(\$2500)] + 0.67[U(\$0)] > 0.34[U(\$2400)] + 0.66[U(\$0)]$, which is equivalent to $0.34[U(\$2400)] < 0.33[U(\$2500)] + 0.01[U(\$0)]$. Notice that preferences for the gambles are inconsistent, that is, from the first preference ordering we deduced that $0.34[U(\$2400)] > 0.33[U(\$2500)] + 0.01[U(\$0)]$, but from the second preference ordering we obtained that $0.34[U(\$2400)] < 0.33[U(\$2500)] + 0.01[U(\$0)]$. Clearly, there is a violation of a prediction from expected utility theory. In an effort to achieve more realistic theories for the perception of the utility of gambles, mathematical psychologists and theoretical economists formulated alternative models. For example, Luce [21] extensively explores alternative utility models in an effort to find a model that more accurately describes the behavior of individuals.

Models of Memory

The modeling of memory has been an active area of research; see [26]. One of the best-known memory models is the Atkinson and Shiffrin multiple-store model [2]. This model deals with both short-term and long-term memory with a system of three memory stores that can be used in a wide variety of ways. The memory stores are a very short-term sensory register, a short-term store, and a permanent memory store. This model stimulated considerable experimental and theoretical research.

The Atkinson and Shiffrin model did not carefully distinguish between recall and recognition behavior measures. These measures are quite different. In subsequent memory research, there has been more attention given to the similarities and differences in recall and recognition measures. In particular, a considerable amount of interest has centered on a class of recognition memory models that has come to be called 'global matching models'. Models in this class differ widely as to the basic representation of information. One type of representation takes a position like that of the Estes array model [8]. For this model, each memory is considered as a separate N -dimensional vector of attributes. A recognition

memory probe activates all of the existing items in the entire memory system by an amount that is dependent on the similarity between the probe and the memory representation. In the Estes array model for classification and recognition, the similarity function between two N -dimensional memory vectors is defined by the expression ts^{N-k} , where t represents the similarity value for the match of k attributes and s is a value between 0 and 1 that is associated with the reduced activation caused by a feature mismatch. The recognition decision is a function of the total similarity produced by the recognition memory probe with all the items in the memory system.

Another model in the global matching class is the Murdock TODAM model [24, 25]. This model uses a distributed representation of information in the memory system. It is assumed that memory is composed of a single vector. The TODAM model does not have separate vectors for various items in memory. Recognition is based on a vector function that depends only on the recognition probe and current state of the memory vector. As more items are added to memory, previous item information may be lost. For TODAM and many other memory models, **Monte Carlo** (i.e., random sampling) methods are used to generate the model predictions for various experimental conditions. In general, these models have a number of parameters – often more parameters than are identifiable in a single condition of an experiment. However, given values for the model parameters, it would be possible to account for the data obtained in that condition as well as many other experimental conditions. In fact, a successful model is usually applied across a wide range of experiments and conditions without major changes in the values for the parameters.

Neural Network Models

Many of the mathematical models of psychological processes fall into the category of **neural networks**. There is also considerable interest in neural network models outside of psychology. For example, physicists modeling materials known as spin glasses have found that neural network models, which were originally developed to explain learning, can also describe the behavior of these substances [4].

In general, there is a distinction between real and artificial neural networks. Real neural networks deal

with brain structures such as the hippocampus or the visual cortex [28]. For real neural networks, the researcher focuses on the functioning of a set of cells or a brain structure as opposed to the behavior of the whole animal. However, artificial neural networks are algorithms mainly for learning and memory, and are more likely to be linked to observable behavior. Artificial neural networks are distributed computing systems that pass information throughout a network (see [1, 23, 29]). As the network ‘experiences’ new input patterns and receives feedback from its ‘behavior’, there are changes in the properties of links and nodes in the network, which in turn affect the behavior of the network. Artificial neural networks have been valuable as models for learning and pattern recognition. There are many possible arrangements for artificial neural network.

Summary

Mathematical psychology is the branch of theoretical psychology that uses mathematics to measure and describe the regularities that are obtained from psychological experiments. Some research in this area (i.e., signal detection theory and multinomial processing tree models) is focused on extracting measures of latent psychological processes from a host of observable measures. Other models in mathematical psychology are focused on the description of the changes in psychological processes across experimental conditions. Examples of this approach would include models of information processing, reaction time, learning, memory, and decision making. The mathematical tools used in mathematical psychology are diverse and reflect the wide range of psychological problems under investigation.

Maximum Likelihood Estimation

Many advanced statistical models (e.g., **structural equation models**) rely on maximum likelihood (ML) estimation. In this entry, we will explore the basic principles of ML estimation using a small data set consisting of 10 scores from the Beck Depression Inventory (BDI) and a measure of perceived social support (PSS). ML parameter estimates are desirable because they are both *consistent* (i.e., the estimate approaches the population parameter as sample size increases) and *efficient* (i.e., have the lowest possible variance, or sampling fluctuation), but these characteristics are asymptotic (i.e., true in large samples). Thus, although these data are useful for pedagogical purposes, it would normally be unwise to use ML with such a small N . The data vectors are as follows.

$$\begin{aligned} \text{BDI} &= [5, 33, 17, 21, 13, 17, 5, 13, 17, 13], \\ \text{PSS} &= [17, 13, 13, 5, 17, 17, 19, 15, 3, 11]. \end{aligned} \quad (1)$$

The goal of ML estimation is to identify the population parameters (e.g., a mean, regression coefficient, etc.) most likely to have produced the sample data (see **Catalogue of Probability Density Functions**). This is accomplished by computing a value called the *likelihood* that summarizes the fit of the data to a particular parameter estimate. Likelihood is conceptually similar to probability, although strictly speaking they are not the same. To determine how ‘likely’ the sample data are, we must first make an assumption about the population score distribution. The normal distribution is frequently used for this purpose.

The shape of a normal curve is described by a complicated formula called a *probability density function* (PDF). The PDF describes the relationship between a set of scores (on the horizontal axis) and the relative probability of observing a given score (on the vertical axis). Thus, the height of the normal curve at a given point along the x -axis provides information about the relative frequency of that score in a normally distributed population with a given mean and variance, μ and σ^2 .

The univariate normal PDF is

$$f(x) = \frac{1}{\sqrt{2\pi\sigma^2}} e^{-[(x-\mu)/\sigma]^2/2}, \quad (2)$$

and is composed of two parts: the term in the exponent is the squared standardized distance from the mean, also known as **Mahalanobis distance**, and the term preceding the exponent is a scaling factor that makes the area under the curve equal to one.

The normal PDF plays a key role in computing the likelihood value for a sample. To illustrate, suppose it was known that the BDI had a mean of 20 and standard deviation of 5 in a particular population. The likelihood associated with a BDI score of 21 is computed by substituting $\mu = 20$, $\sigma = 5$, and $x_i = 21$ into (2) as follows.

$$\begin{aligned} L_i &= \frac{1}{\sqrt{2\pi\sigma^2}} e^{-[(x-\mu)/\sigma]^2/2} \\ &= \frac{1}{\sqrt{2(3.14)(5^2)}} e^{-[(21-20)/5]^2/2} = .078. \end{aligned} \quad (3)$$

The resulting value, .078, can be interpreted as the relative probability of $x_i = 21$ in a normally distributed population with $\mu = 20$ and $\sigma = 5$. Graphically, .078 represents the height of this normal distribution at a value of 21, as seen in Figure 1.

Extending this concept, the likelihood for every case can be computed in a similar fashion, the results of which are displayed in Table 1. For comparative purposes, notice that the likelihood associated with a BDI score of 5 is approximately .001. This tells us that the relative probability of $x_i = 5$ is much lower than that of $x_i = 21$ (.001 versus .078, respectively), owing to the fact that the latter score is more likely to have occurred from a normally distributed population with $\mu = 20$. By extension, this also illustrates that the likelihood associated with a given x_i will change as the population parameters, μ and σ , change.

Table 1 Likelihood and log likelihood values for the hypothetical sample

Case	BDI	Likelihood (L_i)	Log L_i
1	5	.001	-7.028
2	33	.003	-5.908
3	17	.067	-2.708
4	21	.078	-2.548
5	13	.030	-3.508
6	17	.067	-2.708
7	5	.001	-7.028
8	13	.030	-3.508
9	17	.067	-2.708
10	13	.030	-3.508

2 Maximum Likelihood Estimation

Figure 1 Graph of the univariate normal PDF. The height of the curve at $x_i = 21$ represents the relative probability (i.e., likelihood) of this score in a normally distributed population with $\mu = 20$ and $\sigma = 5$

Having established the likelihood for individual x_i values, the likelihood for the sample is obtained via multiplication. From probability theory, the joint probability for a set of independent events is obtained by multiplying individual probabilities (e.g., the probability of jointly observing two heads from independent coin tosses is $(.50)(.50) = .25$). Strictly speaking, likelihood values are not probabilities; the probability associated with any single score from a continuous PDF is zero. Nevertheless, the likelihood value for the entire sample is defined as the product of individual likelihood values as follows:

$$L = \prod_{i=1}^N \left\{ \frac{1}{\sqrt{2\pi\sigma^2}} e^{-[(x_i - \mu)/\sigma]^2/2} \right\}, \quad (4)$$

where Π is the product operator. Carrying out this computation using the individual L_i values from Table 1, the likelihood value for the sample is approximately .000000000000000001327 – a very small number!

Because L becomes exceedingly small as sample size increases, the logarithm of (4) can be used to make the problem more computationally attractive. Recall that one of the rules of logarithms is $\log(ab) = \log(a) + \log(b)$. Applying logarithms to (4) gives the *log likelihood*, which is an additive, rather than multiplicative, model.

$$\log L = \sum_{i=1}^N \log \left\{ \frac{1}{\sqrt{2\pi\sigma^2}} e^{-[(x_i - \mu)/\sigma]^2/2} \right\}. \quad (5)$$

Individual $\log L_i$ values are shown in Table 1, and the log likelihood value for the sample is the sum

of individual $\log L_i$, approximately -41.16 . The log likelihood value summarizes the likelihood that this sample of 10 cases originated from a normally distributed population with parameters $\mu = 20$ and $\sigma = 5$. As can be inferred from the individual L_i values in the table, higher values (i.e., values closer to zero) are indicative of a higher relative probability. As we shall see, the value of the log likelihood can be used to ascertain the ‘fit’ of a sample to a particular set of population parameters.

Thus far, we have worked under a scenario where population parameters were known. More typically, population parameters are unknown quantities that must be estimated from the data. The process of identifying the unknown population quantities involves ‘trying out’ different parameter values and calculating the log likelihood for each. The final *maximum likelihood estimate* (MLE) is the parameter value that produced the highest log likelihood value.

To illustrate, suppose we were to estimate the BDI population mean from the data. For simplicity, assume the population standard deviation is $\sigma = 5$. The sample log likelihood for μ values ranging between 10 and 20 are given in Table 2. Beginning with $\mu = 10$, the log likelihood steadily increases (i.e., improves) until μ reaches a value of 15, after which the log likelihood decreases (i.e., gets worse). Thus, it appears that the MLE of μ is near a value of 15.

The relationship between the population parameters and the log likelihood value, known as the *log likelihood function*, can also be depicted graphically. As seen in Figure 2, the height of the log likelihood

Figure 2 The maximum of the log likelihood function is found at $\mu = 15.4$

Table 2 Log likelihood values for different estimates of the population mean

μ estimate	Log likelihood
10	-42.764
11	-40.804
12	-39.244
13	-38.084
14	-37.324
15	-36.964
16	-37.004
17	-37.444
18	-38.284
19	-39.524
20	-41.164

function reaches a maximum between $\mu = 15$ and 16. More precisely, the function is maximized at $\mu = 15.40$, where the log likelihood takes on a value of -36.9317645 . To confirm this value is indeed the maximum, note that the log likelihood values for $\mu = 15.399$ and 15.401 are -36.9317647 and -36.9617647 , respectively, both of which are smaller (i.e., worse) than the log likelihood produced by $\mu = 15.40$. Thus, the MLE of the BDI population mean is 15.40 , as it is the value that maximizes the log likelihood function. Said another way, $\mu = 15.4$ is the population parameter most likely to have produced this sample of 10 cases.

In practice, the process of ‘trying out’ different parameter values en route to maximizing the log likelihood function is aided by calculus. In calculus, a slope, or rate of change, of a function at a fixed point is known as a *derivative*. To illustrate, tangent lines are displayed at three points on the log likelihood

function in Figure 3. The slope of these lines is the first derivative of the function with respect to μ . Notice that the derivative (i.e., slope) of the function at $\mu = 6$ is positive, while the derivative at $\mu = 24$ is negative. You have probably already surmised that the tangent line has a slope of zero at the value of μ associated with the function’s maximum. Thus, the MLE can be identified via calculus by setting the first derivative to zero and solving for corresponding value of μ on the horizontal axis.

Identifying the point on the log likelihood function where the first derivative equals zero does not ensure that we have located a maximum. For example, imagine a U-shaped log likelihood function where the first derivative is zero at ‘the bottom of the valley’ rather than ‘at the top of the hill’. Fortunately, verifying that the log likelihood function is at its maximum, rather than minimum, can be accomplished by checking the sign of the second derivative. Because second derivatives also play an important role in estimating the variance of an MLE, a brief digression into calculus is warranted.

Suppose we were to compute the first derivative for every point on the log likelihood function. For $\mu < 15.4$, the first derivatives are positive, but decrease in value as μ approaches 15.4 (i.e., the slopes of the tangent lines become increasingly flat close to the maximum). For $\mu > 15.4$, the derivatives become increasingly negative (i.e., more steep) as you move away from the maximum. Now imagine creating a new graph that displays the value of the first derivative (on the vertical axis) for every estimate of μ on the horizontal axis. Such a graph is called a *derivative function*, and second derivatives are defined as the slope of a line tangent to the

Figure 3 First derivatives are slopes of lines tangent to the log likelihood function. The derivative associated with $\mu = 6$ is positive, while the derivative associated with $\mu = 24$ is negative. The derivative is zero at the function's maximum, $\mu = 15.4$

derivative function (i.e., the derivative of a derivative, or rate of change in the slopes). A log likelihood function that is concave down (e.g., Figure 3) would produce a derivative function that begins in the upper left quadrant of the coordinate system (the derivatives are large positive numbers at $\mu < 15.4$), crosses the horizontal axis at the function's maximum value, and continues with a downward slope into the lower right quadrant of the coordinate system (the derivatives become increasingly negative at $\mu > 15.4$). Further, the second derivative (i.e., the slope of a tangent line) at any point along such a function would be negative. In contrast, the derivative function for a U-shaped log likelihood would stretch from the upper right quadrant to the lower left quadrant, and would produce a positive second derivative. Thus, a negative second derivative verifies that the log likelihood function is at a maximum.

Identifying the MLE is important, but we also want to know how much uncertainty is associated with an estimate – this is accomplished by examining the parameter's standard error. The variance of an MLE, the square root of which is its standard error, is also a function of the second derivatives. In contrast to Figure 2, imagine a log likelihood function that is very flat. The first derivatives, or slopes, would change very little from one value of μ to the next. One way to think about second derivatives is that they quantify the rate of change in the first derivatives. A high rate of change in the first derivatives (e.g., Figure 2) reflects greater certainty about the parameter estimate (and thus a lower standard error), while

derivatives that change very little (e.g., a relatively flat log likelihood function) would produce a larger standard error. When estimating multiple parameters, the matrix of second derivatives, called the **information matrix**, is used to produce a covariance matrix (see **Correlation and Covariance Matrices**) of the parameters (different from a covariance matrix of scores), the diagonal of which reflects the variance of the MLEs. The standard errors are found by taking the square root of the diagonal elements in the parameter covariance matrix.

Having established some basic concepts, let us examine a slightly more complicated scenario involving multiple parameters. To illustrate, consider the regression of BDI scores on PSS. There are now two parameters of interest, a regression intercept, β_0 , and slope, β_1 (see **Multiple Linear Regression**). The log likelihood given in (5) is altered by replacing μ with the conditional mean from the regression equation (i.e., $\mu = \beta_0 + \beta_1 x_{1i}$).

$$\log L = \sum_{i=1}^N \log \left\{ \frac{1}{\sqrt{2\pi\sigma^2}} e^{-[(y_i - \beta_0 - \beta_1 x_{1i})/\sigma]^2/2} \right\}. \quad (6)$$

Because there are now two unknowns, estimation involves 'trying out' different values for both β_0 and β_1 . Because the log likelihood changes as a function of two parameters, the log likelihood appears as a three-dimensional surface. In Figure 4, the values of β_0 and β_1 are displayed on separate axes, and the vertical axis gives the value of the log likelihood for every combination of β_0 and β_1 . A precise solution

Figure 4 Log likelihood surface for simple regression estimation. ML estimates of β_0 and β_1 are 23.93 and $-.66$, respectively

for β_0 and β_1 relies on the calculus concepts outlined previously, but an approximate maximum can be identified at the intersection of $\beta_0 = 25$ and $\beta_1 = -.60$ (the ML estimates obtained from a model-fitting program are $\beta_0 = 23.93$ and $\beta_1 = -.66$).

Standard errors for the MLEs are obtained as a function of the second derivatives, and can be used to construct single-parameter significance tests of the null hypothesis, $\beta_j = 0$. Because the asymptotic sampling distribution for an MLE is itself a normal distribution, a z test is constructed by dividing the parameter estimate by its *asymptotic standard error* (ASE), the square root of the appropriate diagonal element in the parameter covariance matrix.

$$z = \frac{\hat{\beta} - 0}{ASE(\hat{\beta})}. \quad (7)$$

To illustrate, the ASE for β_1 is .429, and the corresponding z ratio is $-.656/.429 = -1.528$. This z ratio can subsequently be compared to a critical value obtained from the unit normal table. For example, the critical value for a two-tailed test using $\alpha = .05$ is ± 1.96 , so β_1 is not significantly different from zero. The ASEs can also be used to construct confidence intervals around the MLEs in the usual fashion.

A more general strategy for conducting significance tests involves comparing log likelihood values

from two nested models. Models are said to be nested if the parameters of one model (i.e., the ‘reduced’ model) are a subset of the parameters from a second model (i.e., the ‘full’ model). For example, consider a multiple regression analysis with five predictor variables, x_1 through x_5 . After obtaining MLEs of the regression coefficients, suppose we tested a reduced model involving only x_1 and x_2 . If the log likelihood changed very little after removing x_3 through x_5 , we might reasonably conclude that this subset of predictors is doing little to improve the fit of the model – conceptually, this is similar to testing a set of predictors using an F ratio.

More formally, the likelihood ratio test is defined as the difference between $-2 \log L$ values (sometimes called the *deviance*) for the full and reduced model. This difference is asymptotically distributed as a chi-square statistic with degrees of freedom equal to the difference in the number of estimated parameters between the two models. A nonsignificant likelihood ratio test indicates that the fit of the reduced model is not significantly worse than that of the full model. It should be noted that the likelihood ratio test is only appropriate for use with nested models, and could not be used to compare models with different sets of predictors, for example. Likelihood-based indices such as the Bayesian Information Criterion (BIC) can

instead be used for this purpose (*see Bayesian Statistics*).

The examples provided thus far have relied on the univariate normal PDF. However, many common statistical models (e.g., structural equation models) are derived under the multivariate normal PDF, a generalization of the univariate normal PDF to $k \geq 2$ dimensions. The multivariate normal distribution (*see Catalogue of Probability Density Functions*) can only be displayed graphically in three dimensions when there are two variables, and in this case the surface of the bivariate normal distribution looks something like a bell-shaped ‘mound’ (e.g., see [2, p. 152]).

The multivariate normal PDF is

$$f(\mathbf{x}) = \frac{1}{(2\pi)^{p/2} |\boldsymbol{\Sigma}|^{1/2}} e^{-(\mathbf{x}-\boldsymbol{\mu})' \boldsymbol{\Sigma}^{-1} (\mathbf{x}-\boldsymbol{\mu})/2}. \quad (8)$$

In (8), $\mathbf{x}$ and $\boldsymbol{\mu}$ are vectors of scores and means, respectively, and $\boldsymbol{\Sigma}$ is the covariance matrix of the scores. Although (8) is expressed using vectors and matrices, the major components of the PDF remain the same; the term in the exponent is a multivariate extension of Mahalanobis distance that takes into account both the variances and covariances of the scores, and the term preceding the exponent is a scaling factor that makes the volume under the density function equal to one (in the multivariate case, probability values are expressed as volumes under the surface).

Consistent with the previous discussion, estimation proceeds by ‘trying out’ different values for $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ in search for estimates that maximize the log likelihood. Note that in some cases the elements of $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ may not be the ultimate parameters of interest but may be functions of model parameters (e.g., $\boldsymbol{\Sigma}$ may contain covariances predicted by the parameters from a structural equation model, or $\boldsymbol{\mu}$ may be a function of regression coefficients from a **hierarchical model**). In any case, an individual’s contribution to the likelihood is obtained by substituting her vector of scores, $\mathbf{x}$, into (8) and solving, given the estimates for $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$. As before, the sample likelihood is the product of (8) over the N cases, and the log likelihood is obtained by summing the logarithm of (8) over the N cases.

The estimation of multiple parameters generally requires the use of iterative numerical optimization techniques to maximize the log likelihood. One such

technique, the estimation maximization (EM) algorithm, is discussed in detail in [11], and these algorithms are discussed in more detail elsewhere [1]. Conceptually, the estimation process is much like climbing to the top of a hill (i.e., the log likelihood surface), similar to that shown in Figure 4. The first step of the iterative process involves the specification of initial values for the parameters of interest. These *starting values* may, in some cases, be provided by the analyst, and in other cases are arbitrary values provided automatically by the model-fitting program. The choice of different starting values is tantamount to starting the climb from different locations on the topography of the log likelihood surface, so a good set of starting values may reduce the number of ‘steps’ required to reach the maximum. In any case, these initial values are substituted into the multivariate PDF to obtain an initial log likelihood value. In subsequent iterations, adjustments to the parameter estimates are chosen such that the log likelihood consistently improves (this is accomplished using derivatives), eventually reaching its maximum. As the solution approaches its maximum, the log likelihood value will change very little between subsequent iterations, and the process is said to have converged if this change falls below some threshold, or *convergence criterion*.

Before closing, it is important to distinguish between full maximum likelihood (FML) and restricted maximum likelihood (RML), both of which are commonly implemented in model-fitting programs. Notice that the log likelihood obtained from the multivariate normal PDF includes a mean vector, $\boldsymbol{\mu}$, and a covariance matrix, $\boldsymbol{\Sigma}$. FML estimates these two sets of parameters simultaneously, but the elements in $\boldsymbol{\Sigma}$ are not adjusted for the uncertainty associated with the estimation of $\boldsymbol{\mu}$ – this is tantamount to computing the variance using N rather than $N - 1$ in the denominator. As such, FML variance estimates will exhibit some degree of negative bias (i.e., they will tend to be too small), particularly in small samples. RML corrects this problem by removing the parameter estimates associated with $\boldsymbol{\mu}$ (e.g., regression coefficients) from the likelihood. Thus, maximizing the RML log likelihood only involves the estimation of parameters associated with $\boldsymbol{\Sigma}$ (in some contexts referred to as **variance components**). Point estimates for $\boldsymbol{\mu}$ are still produced when using RML, but these parameters are

estimated in a separate step using the RML estimates of the variances and covariances.

In practice, parameter estimates obtained from FML and RML tend to be quite similar, perhaps trivially different in many cases. Nevertheless, the distinction between these two methods has important implications for hypothesis testing using the likelihood ratio test. Because parameters associated with μ (e.g., regression coefficients) do not appear in the RML likelihood, the likelihood ratio can only be used to test hypotheses involving variances and covariances. From a substantive standpoint, these tests are often of secondary interest, as our primary hypotheses typically involve means, regression coefficients, etc. Thus, despite the theoretical advantages associated with RML, FML may be preferred in many applied research settings, particularly given that the two approaches tend to produce similar variance estimates.

In closing, the intent of this manuscript was to provide the reader with a brief overview of the basic principles of ML estimation. Suffice to say, we have only scratched the surface in the short space allotted here, and interested readers are encouraged to consult more detailed sources on the topic [1].

Maximum Likelihood Item Response Theory Estimation

Owing to a variety of theoretical and computational advances in the last 15 years, measurement literature has seen an upsurge in the theoretical development of modeling approaches and the practical development of routines for estimating their constituent parameters [10, 16, 19]. Despite the methodological and technical variety of these approaches, however, several common principles and approaches underlie the parameter estimation processes for them. This entry reviews these principles and approaches but, for more in-depth readings, a consultation of the comprehensive book by Baker [1], the didactic on the expectation maximization (EM)-algorithm by Harwell, Baker, and Zwarts [8] and its extension to Bayesian estimation (*see* **Bayesian Statistics; Bayesian Item Response Theory Estimation**) by Harwell and Baker [7], the technical articles on estimation with the EM-algorithm by Bock and Aitkin [2], Bock and Lieberman [3], Dempster, Laird, and Rubin [5], and Mislevy [11, 12], as well as the review article by Rupp [20], are recommended.

Conceptual Foundations for Parameter Estimation

The process of calibrating statistical models is generally concerned with two different sets of parameters, one set belonging to the assessment items and one set belonging to the examinees that interact with the items. While it is common to assign labels to item parameters such as ‘difficulty’ and ‘guessing’, no such meaning is strictly implied by the statistical models and philosophical considerations regarding parameter interpretation, albeit important, are not the focus here.

In this entry, examinees are denoted by $i = 1, \dots, I$, items are denoted by $j = 1, \dots, J$, the latent predictor variable (*see* **Latent Variable**) is unidimensional and denoted by θ , and the response probability for a correct response to a given item or item category is denoted by P or, more specifically, by $P_j(X_{ij} = x_{ij}|\theta)$. The following descriptions will

be general and, therefore, will leave the specific functional form that separates different latent variable models unspecified. However, as an example, one may want to consider the unidimensional three-parameter logistic model from item response theory (IRT) (*see* **Item Response Theory (IRT) Models for Polytomous Response Data; Item Response Theory (IRT) Models for Rating Scale Data**), with the functional form

$$P_j(X_{ij} = x_{ij}|\theta) = \gamma_j + (1 - \gamma_j) \frac{\exp[\alpha_j(\theta - \beta_j)]}{1 + \exp[\alpha_j(\theta - \beta_j)]}. \quad (1)$$

To better understand common estimation approaches, it is necessary to understand a fundamental assumption that is made by most latent variable models, namely, that of *conditional* or *local independence*. This assumption states that the underlying data-generation mechanism for an observed data structure, as formalized by a statistical model, is of that dimensionality d that renders responses to individual items independent of one another for any given person. As a result, the *conditional* probability of observing a response vector $\mathbf{x}_i$ for a given examinee can then be expressed as

$$P(\mathbf{X}_i = \mathbf{x}_i|\theta) = \prod_{j=1}^J P_j(X_{ij} = x_{ij}|\theta). \quad (2)$$

Given that the responses of the examinees are independent of one another, because examinees are typically viewed as randomly and independently sampled from a population of examinees with latent variable distribution $g(\theta)$ [9], the *conditional* probability of observing all response patterns (i.e., the *conditional* probability of observing the data) can, therefore, be expressed as the double-product

$$P(\mathbf{X} = \mathbf{x}|\theta) = \prod_{i=1}^I \prod_{j=1}^J P_j(X_{ij} = x_{ij}|\theta). \quad (3)$$

This probability, if thought of as a function of θ , is also known as the *likelihood* for the data, $L(\theta|\mathbf{X} = \mathbf{x})$. Under the assumption of θ as a random effect, one can further integrate out θ to obtain the *unconditional* or *marginal probability* of observing

2 Maximum Likelihood IRT Estimation

the data,

$$P(\mathbf{X} = \mathbf{x}) = \prod_{i=1}^I \left\{ \int_{\Theta} \prod_{j=1}^J P_j(X_{ij} = x_{ij} | \theta_i) g(\theta) d\theta \right\}, \quad (4)$$

also known as the *marginal likelihood* for the data. Here, $g(\theta)$ denotes the probability distribution of θ in the population, which is often assumed to be standard normal but which can, technically, be of any form as long as it has interval-scale support on the real numbers.

However, while (3) and (4) are useful for a conceptual understanding of the estimation routines, it is numerically easier to work with their logarithmic counterparts. Hence, one obtains, on the basis of (3), the *log-likelihood* of the data ($\log -L$),

$$\log -L = \sum_{i=1}^I \sum_{j=1}^J \log [P_j(X_{ij} = x_{ij} | \theta)] \quad (5)$$

and, based on (4), the *marginal log-likelihood* of the data ($\log -L_M$),

$$\log -L_M = \sum_{i=1}^I \log \left\{ \int_{\Theta} \prod_{j=1}^J P_j(X_{ij} = x_{ij} | \theta) g(\theta) d\theta \right\}, \quad (6)$$

which are theoretical expressions that include latent θ values that need to be estimated for practical implementation.

Estimation of θ Values

Estimating latent θ values amounts to replacing them by manifest values from a finite subset of the real numbers. This requires the establishment of a latent variable metric and a common latent variable metric is one with a mean of 0 and a standard deviation of 1. Consequently, one obtains the estimated counterparts to (3 and 5), which are the *estimated likelihood*,

$$\tilde{P}(\mathbf{X} = \mathbf{x} | \theta) \cong \prod_{i=1}^I \prod_{j=1}^J \tilde{P}_j(X_{ij} = x_{ij} | T) \quad (7)$$

and the *estimated log-likelihood*,

$$\log -\tilde{L} \cong \sum_{i=1}^I \sum_{j=1}^J \log [\tilde{P}_j(X_{ij} = x_{ij} | T)] \quad (8)$$

where the letter T is used to denote that manifest values are used and $\tilde{P}$ indicates that this results in an estimated probability. Similarly, (4 and 6) require the estimation of the distribution $g(\theta)$ where, again, a suitable subset of the real numbers is selected (e.g., the interval from -4 to 4 if one assumes that $\theta \sim N(0, 1)$), along with a number of K evaluation points that are typically selected to be equally spaced in that interval. For each evaluation point, the approximate value of the selected density function is then computed, which can be done for a theoretically selected distribution (e.g., a standard normal distribution) or for an empirically estimated distribution (i.e., one that is estimated from the data). For example, in BILOG-MG [24] and MULTILOG [22], initial density weights, also known as *prior density weights*, are chosen to start the estimation routine, which then become adjusted or replaced at each iteration cycle by empirically estimated weights, also known as *posterior density weights* [11].

If one denotes the k th density weight by $A(T_k)$, one thus obtains, as a counterpart to (4), the *estimated marginal likelihood*,

$$\tilde{P}(\mathbf{X} = \mathbf{x}) = \prod_{i=1}^I \left[\sum_{k=1}^K \left\{ \prod_{j=1}^J \tilde{P}_j(X_{ij} = x_{ij} | T_k) \right\} A(T_k) \right] \quad (9)$$

and, as a counterpart to (6), the *estimated marginal log-likelihood*,

$$\begin{aligned} \log -\tilde{L}_M &= \sum_{i=1}^I \log \left[\sum_{k=1}^K \left\{ \prod_{j=1}^J P_j(X_{ij} = x_{ij} | T_k) \right\} A(T_k) \right] \end{aligned} \quad (10)$$

where, again, the letter T is used to denote that manifest values are used and $\tilde{P}$ indicates that this results in an estimated probability. With these equations at hand we are now ready to discuss the three most common estimation approaches, *Joint Maximum*

Likelihood (JML), Conditional Maximum Likelihood (CML), and Marginal Maximum Likelihood (MML).

JML and CML Estimation

Historically, JML was the approach of choice for estimating item and examinee parameters. It is based on an *iterative estimation scheme* that cyclically estimates item and examinee parameters by computing the partial derivatives of the $\log -L$ (see (6 and 8)) with respect to these parameters, setting them equal to 0, and solving for the desired parameter values. At each step, provisional parameter estimates from the previous step are used to obtain updated parameter estimates for the current step. While this approach is both intuitively appealing and practically relatively easy to implement, it suffers from theoretical drawbacks. Primarily, it can be shown that the resulting parameter estimates are *not consistent*, which means that, asymptotically, they do *not* become arbitrarily close to their population targets in probability, which would be desirable [4, p. 323]. This is understandable, however, because, with each additional examinee, an additional incidental θ parameter is added to the pool of parameters to be estimated and, with each additional item, a certain number of structural item parameters is added as well, so that increasing either the number of examinees or the number of items does not improve asymptotic properties of the joint set of estimators.

An alternative estimation approach is CML, which circumvents this problem by replacing the unknown θ values directly by values of manifest statistics such as the *total score*. For this approach to behave properly, however, the manifest statistics have to be *sufficient for θ* , which means that they have to contain all available information in the data about θ and have to be directly computable. In other words, the use of CML is restricted to classes of models with *sufficient statistics* such as the Rasch model in IRT [6, 23]. Since the application of CML is restricted to subclasses of models and JML does not possess optimal estimation properties, a different approach is needed, which is the niche that MML fills.

MML Estimation

The basic idea in MML is similar to CML, namely, to overcome the theoretical inconsistency

of item parameter estimators and to resolve the iterative dependency of previous parameter estimates in JML. This is accomplished by first integrating out θ (see (4 and 6)) and then maximizing the $\log -L_M$ (see (9 and (10)) to obtain the MML estimates of the item parameters using first- and second-order derivatives and a numerical algorithm such as Newton–Raphson for solving the equations involved. The practical maximization process of (10) is done via a modification of a missing-data algorithm, the EM algorithm [2, 3, 5]. This algorithm uses the *expected* number of examinees at each evaluation point, $\bar{n}_{jk}$, and the *expected* number of correct responses at each evaluation point, $\bar{r}_{jk}$, as ‘artificial’ data and then maximizes the $\log -L_M$ at each iteration.

Specifically, the EM algorithm employs *Bayes Theorem* (see **Bayesian Belief Networks**). In general, the theorem expresses the *posterior probability* of an event, after observing the data, as a function of the *likelihood* for the data and the *prior probability* of the event, before observing the data. In order to implement the EM algorithm, the kernel of the $\log -L_M$ is expressed with respect to the *posterior probability for θ* , which is

$$P_i(\theta|\mathbf{X}_i = \mathbf{x}_i) = \frac{L(\mathbf{X}_i = \mathbf{x}_i|\theta)h(\theta)}{\int_{\Theta} L(\mathbf{X}_i = \mathbf{x}_i|\theta)h(\theta)d\theta} \quad (11)$$

where $h(\theta)$ is a *prior distribution* for θ . Using this theorem, the MML estimation process within the EM algorithm is comprised of three steps, which are repeated until *convergence* of the item parameter estimates is achieved.

First, the posterior probability of θ for each examinee i at each evaluation point k is computed via

$$P_{ik}(T_k|\mathbf{X}_i) = \frac{\left\{ \prod_{j=1}^J P_j(X_{ij} = x_{ij}|T_k) \right\} A(T_k)}{\sum_{s=1}^K \left\{ \prod_{j=1}^J P_j(X_{ij} = x_{ij}|T_s) \right\} A(T_s)} \quad (12)$$

as an approximation to (11) at evaluation point k . This is accomplished by using *provisional* item parameter estimates from the previous iteration to

compute $P_j(X_{ij} = x_{ij}|T_k)$ for a chosen model. Second, using these posterior probabilities, the artificial data for each item j at each evaluation point k are generated using

$$\begin{aligned}\bar{n}_{jk} &= \sum_{i=1}^I P_{ik}(T_k|\mathbf{X}_i) \\ \bar{r}_{jk} &= \sum_{i=1}^I X_{ij} P_{ik}(T_k|\mathbf{X}_i).\end{aligned}\quad (13)$$

Third, the first-order derivatives of the estimated $\log -L_M$ function in (10) with respect to the item parameters are set to 0 and are solved for the item parameters. In addition, the information matrix at these point estimates is computed using the Newton–Gauss/Fisher scoring algorithm to estimate their precision. For that purpose, (10) and its derivatives are rewritten using the artificial data; the entire process is then repeated until convergence of parameter estimates has been achieved. Instead of just performing the above steps, however, programs such as BILOG-MG and MULTILOG allow for a fully Bayesian estimation process. In that framework, additional prior distributions can be specified for *all* item parameters and *all* examinee distribution parameters, which are then incorporated into the $\log -L_M$ and its derivatives where they basically contribute additive terms. Finally, it should be noted that it is common to group examinees by observed response patterns and to use the observed frequencies of each response pattern to reduce the number of computations but that step is not reproduced in this exposition to preserve notational clarity.

Thus, rather than obtaining individual θ estimates, in MML one obtains item parameter estimates and only the distribution parameters of $g(\theta)$. Nevertheless, if subsequently desired, the item parameter estimates can be used as ‘known’ values to obtain estimates of the examinee parameters using *maximum likelihood (ML)*, Bayesian *expected a posteriori (EAP)* or Bayesian *maximum a posteriori (MAP)* estimation and their precision can be estimated using the *estimated information matrices* at the point estimates for the ML approach, the *estimated standard deviation of the posterior distributions* for the EAP approach, or the *estimated posterior information matrices* for the MAP approach.

Alternative Estimation Approaches

While JML, CML, and, specifically, MML within a fully Bayesian framework, are the most flexible estimation approaches, extensions of these approaches and other parameter estimation techniques exist. For example, it is possible to incorporate collateral information about examinees into the MML estimation process to improve its precision [13]. Nonparametric models sometimes require techniques such as principal components estimation [15] or kernel-smoothing [18]. More complex psychometric models, as commonly used in cognitively diagnostic assessment, for example, sometimes require specialized software routines altogether [14, 17, 21]. Almost all estimation approaches are based on the foundational principles presented herein, which substantially unify modeling approaches from an estimation perspective.

Maxwell, Albert Ernest

Born: July 7, 1916, in County Cavan.

Died: 1996, in Leeds.

Albert Ernest Maxwell, always known as ‘Max’, is remembered primarily in the research community for his collaboration with D. N. Lawley in producing the monograph *Factor Analysis as a Statistical Method*. The first edition was published as one of Butterworth’s mathematical texts in 1963, with a reprint four years later [3] (see also [2]). The second edition followed in 1971 with publication in the United States by American Elsevier. The second edition was larger in all senses of the word and included new work by Jöreskog and others on fitting the factor model by maximum likelihood. It also contained new results on the sampling behavior of the estimates. The title of the book is significant. Up to its appearance, **factor analysis** (which had been invented by **Spearman** in 1904) had been largely developed within the psychological community – although it had points of contact with **principal component analysis** introduced by **Harold Hotelling** in 1933. Factor analysis had been largely ignored by statisticians, though **M. G. Kendall** and M. S. Bartlett were notable exceptions. More than anyone else, Lawley and Maxwell brought factor analysis onto the statistical stage and provided a definitive formulation of the factor model and its statistical properties. This is still found, essentially unchanged, in many contemporary texts. It would still be many years, however, before the prejudices of many statisticians would be overcome and the technique would obtain its rightful place in the statistical tool kit. That it has done so is due in no small measure to Maxwell’s powers of exposition as a writer and teacher. Maxwell, himself, once privately expressed a pessimistic view of the reception of this book by the statistical community but its long life and frequent citation belie that judgment.

Less widely known, perhaps, was his role as a teacher of statistics in the behavioral sciences. This was focused on his work at the Institute of Psychiatry in the University of London where he taught and advised from 1952 until his retirement in 1978. The distillation of these efforts is contained in another small but influential monograph *Multivariate Analysis in Behavioural Research* published in 1977 [5].

This ranged much more widely than factor analysis and principal components analysis, and included, for example, a chapter on the **analysis of variance** in matrix notation, which was more of a novelty when it was published in 1977 than it would be now. The book was clear and comprehensive but, perhaps, a little too concise for the average student. But, backed by good teaching, such as that Maxwell provided, it must have made a major impact on generations of research workers. Unusually perhaps, space was found for a chapter on the analysis of **contingency tables**. This summarized a topic that had been the subject of another of his earlier, characteristically brief, monographs, this time *Analysing Qualitative Data* from 1964 [4]. A final chapter by his colleague, Brian Everitt, introduced **cluster analysis**. The publication of Everitt’s monograph on that subject, initially on behalf of the long defunct UK Social Science Research Council (SSRC), was strongly supported by Maxwell [1].

Much of the best work by academics is done in the course of advisory work, supervision, refereeing, committee work, and so forth. This leaves little mark on the pages of history, but Maxwell’s role at the Institute and beyond made full use of his talents in that direction. Outside the Institute, he did a stint on the Statistics Committee of the SSRC where his profound knowledge of psychological statistics did much to set the course of funded research in his field as well as, occasionally, enlightening his fellow committee members.

Maxwell’s career did not follow the standard academic model. He developed an early interest in psychology and mathematics at Trinity College, Dublin. This was followed by a spell as a teacher at St. Patrick’s Cathedral School in Dublin of which he became the headmaster at the age of 25. His conversion to full-time academic work was made possible by the award of a Ph.D. from the University of Edinburgh in 1950. Two years later, he left teaching and took up a post as lecturer in statistics at the Institute of Psychiatry, where he remained for the rest of his working life. Latterly, he was head of the Biometrics unit at the Institute.

Measurement: Overview

Behavioral science admits a diverse class of practices under the heading of measurement. These extend beyond the measurement of physical and biological attributes and include transformations of frequencies (e.g., in psychometrics), summated ratings (e.g., in social psychology), and direct numerical estimates of subjective magnitudes (e.g., in psychophysics). These are used in the hope of measuring specifically psychological attributes and are important sources of data for statistical analyses in behavioral science.

Since the Second World War, the consensus within this science has been that *measurement* is ‘the assignment of numerals to objects or events according to rules’ [38 p. 667], a definition of measurement unique to social and behavioral science. Earlier definitions, such as the one suggested by the founder of quantitative behavioral science, **G. T. Fechner** [7], that ‘the measurement of a quantity consists of ascertaining how often a unit quantity of the same kind is contained in it’ (p. 38), reflect traditional quantitative science. More recent definitions, for example that ‘measurement is (or should be) a process of assigning numbers to objects in such a way that interesting qualitative empirical relations among the objects are reflected in the numbers themselves as well as in important properties of the number system’ [43 p. 394] are shaped by modern measurement theory. Recent dictionary entries, like Colman’s [5], defining measurement as the ‘systematic assignment of numbers to represent quantitative attributes of objects or events’ (p. 433), also reveal a shift from the earlier consensus. Tensions between the range of practices behavioral scientists call *measurement*, the way measurement is defined in traditional quantitative science, and various concepts of measurement within philosophy of science are responsible for this definitional diversity.

The Traditional Concept of Measurement

The traditional concept of measurement derives from Euclid’s *Elements* [10]. The category of *quantity* is central. An attribute is quantitative if its levels sustain ratios. Take length, for example. Any pair of lengths, l_1 and l_2 , interrelate additively, in the sense that there exist whole numbers, n and m , such that $nl_1 > l_2$ and

$ml_2 > l_1$. Prior to Euclid, a magnitude of a quantity, such as a specific length, was said to be *measured* by the number of units which, when added together, equaled it exactly. Such a concept of measurement does not accommodate all pairs of magnitudes, in particular, it does not accommodate incommensurable pairs. It was known that there are some pairs of lengths, for example, for which there are no whole numbers n and m such that n times the first exactly spans m times the second (e.g., the side and diagonal of a square) and that, therefore, for such pairs, the measure of the first relative to the second does not equal a numerical ratio (i.e., a ratio of two whole numbers). It was a major conceptual breakthrough to recognize (as Book V of Euclid’s *Elements* suggests) that the ratio of any pair of magnitudes, such as lengths, l_1 and l_2 (including incommensurable pairs) always falls between two infinite classes of numerical ratios as follows:

$$\{\text{the class of ratios of } n \text{ to } m\} < \text{the ratio of } l_1 \text{ to } l_2 \\ < \{\text{the class of ratios of } p \text{ to } q\}$$

(where n , m , p , and q range over all whole numbers such that $nl_2 < ml_1$ and $ql_1 < pl_2$). This meant that the measure of l_1 relative to l_2 could be understood as the positive *real number* (as it became known, much later, toward the end of the nineteenth century [6]) falling between these two classes.

This breakthrough not only explained the role of numbers in measurement, it also provided a guide to the internal structure of quantitative attributes: they are attributes in which ratios between any two levels equal positive real numbers. The German mathematician, Otto Hölder [12] (see also [27] and [28]) was the first to characterize the structure of unbounded, continuous, quantitative attributes and his seven axioms of quantity are similar to the following set [26] applying to lengths. Letting a , b , c , $\dots$, be any specific lengths and letting $a + b = c$ denote the relation holding between lengths a , b , and c when c is entirely composed of discrete parts, a and b :

1. For every pair of lengths, a and b , one and only one of the following is true:
 - (i) $a = b$;
 - (ii) there exists another length, c , such that $a = b + c$;
 - (iii) there exists another length, d , such that $b = a + d$.

2 Measurement: Overview

2. For any lengths a and b , $a + b > a$.
3. For any lengths a and b , $a + b = b + a$.
4. For any lengths a, b , and c , $a + (b + c) = (a + b) + c$.
5. For any length a , there is another length, b , such that $b < a$.
6. For any lengths a and b there is another length, c such that $c = a + b$.
7. For every nonempty class of lengths having an upper bound, there is a least upper bound.

(Note that an upper bound of a class of lengths is any length not less than any member of the class and that a least upper bound is an upper bound not greater than any other upper bound). The first four of these conditions state what it means for lengths to be additive. The remaining three ensure that the characterization excludes no lengths (i.e., there is no greatest or least length, nor gaps in the ordered series of them). All measurable, unbounded, continuous, quantitative attributes of physics (e.g., length, mass, time, etc.) are taken to possess this kind of structure. Hölder proved that ratios between levels of any attribute having this kind of structure possess the structure of the positive real numbers. This is a necessary condition for the identification of such ratios by real numbers.

If quantitative attributes are taken to have this kind of structure, then the meaning of measurement is explicit: *measurement is the estimation of the ratio between a magnitude of a quantitative attribute and a unit belonging to the same attribute*. This is the way measurement is understood in physics. For example,

Quantities are abstract concepts possessing two main properties: they can be measured, that means that the ratio of two quantities of the same kind, a pure number, can be established by experiment; and they can enter into a mathematical scheme expressing their definitions or the laws of physics. A unit for a kind of quantity is a sample of that quantity chosen by convention to have the value 1. So that, as already stated by Clerk Maxwell,

$$\text{physical quantity} = \text{pure number} \times \text{unit}. \quad (1)$$

This equation means that the ratio of the quantitative abstract concept to the unit is a pure number [41 pp. 765–766].

Measurement in physics is the fixed star relative to which measurement in other sciences steer. There always have been those who believe that behavioral

scientists must attempt to understand their quantitative practices within the framework of the traditional concept of measurement (see [25] and [26]).

However, from the time of **Fechner, Gustav T.**, it was questioned (e.g., see [45]) whether the attributes thought to be measurable within behavioral science also possess quantitative structure. As posed relative to the traditional concept of measurement, this question raised an issue of evidence: on what scientific grounds is it reasonable to conclude that an attribute possesses quantitative structure? In an important paper [11], the German scientist, Hermann von Helmholtz, made the case that this issue of evidence is solved for physical, quantitative attributes.

Helmholtz argued that evidence supporting the conclusion that the attributes measured in physical science are quantitative comes in two forms, namely, those later designated *fundamental* and *derived* measurement by Campbell [2]. In the case of fundamental measurement, evidence for quantitative structure is gained via an empirical operation for concatenating objects having different levels of the attribute, which results in those levels adding together. For example, combining rigid, straight rods linearly, end to end adds their respective lengths; placing marbles together in the same pan of a beam balance adds their respective weights; and starting a second process contiguous with the cessation of a first adds their respective durations. In this regard, the seven conditions given above describing the structure of a quantitative attribute are not causal laws. In and of themselves, they say nothing about how objects possessing levels of the attribute will behave under different conditions. These seven conditions are of the kind that J. S. Mill [29] called *uniformities of coexistence*. They specify the internal structure of an attribute, not the behavior of objects or events manifesting magnitudes of the attribute. This means that there is no logical necessity that fundamental measurement be possible for any attribute. That it is for a number of attributes (e.g., the geometric attributes, weight, and time), albeit in each case only for a very limited range of levels, is a happy accident of nature.

In the case of derived measurement, evidence for quantitative structure is indirect, depending upon relations between attributes already known to be quantitative and able to be measured. That a theoretical attribute is quantitative is indicated via derived measurement when objects believed to be equivalent with respect to the attribute also manifest a

constancy in some quantitative function of other, measurable attributes, as, for example, the ratio of mass to volume for different objects, all composed of the same kind of substance, is always a numerical constant. Then it seems reasonable to infer that the theoretical attribute is quantitative and measured by the relevant quantitative function. Since physical scientists have generally restricted the claim that attributes are quantitative to those to which either fundamental or derived measurement apply, there is little controversy, although some attributes, such as temperature, remained controversial longer than others (see, e.g., [22]). However, regarding the nonphysical attributes of behavioral science, the question of evidence for quantitative structure remained permanently controversial.

Nonetheless, and despite the arguments of Fechner's critics, the traditional concept of measurement provided no basis to reject the hypothesis that psychological attributes are quantitative. At most, it indicated a gap in the available evidence for those wishing to accept this hypothesis as an already established truth.

The Representational Concept of Measurement

By the close of the nineteenth century, the traditional concept of measurement was losing support within the philosophy of science and early in the twentieth century, the representational concept became dominant within that discipline. This was because thinking had drifted away from the traditional view of number (i.e., that they are ratios of quantities [32]) and toward the view that the concept of number is logically independent of the concept of quantity [35]. If these concepts are logically unrelated, then an alternative to the traditional account of measurement is required. Bertrand Russell suggested the representational concept, according to which measurement depends upon the existence of isomorphisms between the internal structure of attributes and the structure of subsystems of the real numbers. Since Hölder's paper [12] proves an isomorphism between quantitative attributes and positive real numbers, the representational concept fits all instances of physical measurement as easily as the traditional concept. Where the representational concept has an edge over the traditional concept is

in its capacity to accommodate the numerical representation of nonquantitative attributes. Chief amongst these are so-called *intensive magnitudes*.

While the concept of intensive magnitude had been widely discussed in the later middle ages, by the eighteenth century, its meaning had altered (see [14]). For medieval scholars, an intensive magnitude was an attribute capable of increase or decrease (i.e., what would now be called an *ordinal attribute*) understood by analogy with quantitative structure and, thereby, hypothesized to be both quantitative and measurable. Nineteenth century scholars, likewise, thought of an intensive magnitude as an attribute capable of increase or decrease, but it was thought of as one in which each degree is an indivisible unity and not able to be conceptualized as composed of parts and, so, it was one that could not be quantitative. While some intensive attributes, such as temperature was then believed to be, were associated with numbers, the association was thought of as 'correct only as to the more or less, not as to the how much' as Russell [34 p. 55] put it.

Many behavioral scientists, retreating in the face of Fechner's critics, had, by the beginning of the twentieth century, agreed that different levels of sensation were only intensive magnitudes and not fully quantitative in structure. Titchener [42 p. 48] summarized this consensus (using *S* to stand for sensation):

Now it is clear that, in a certain sense, the *S* may properly be termed a magnitude (*Grösse, grandeur*): in the sense, namely, that we speak of a 'more' and 'less' of *S*-intensity. Our second cup of coffee is sweeter than the first; the water today is colder than it was yesterday; *A*'s voice carries farther than *B*'s. On the other hand, the *S* is not, in any sense, a quantity (*messbare Grösse, Quantität, quantité*).

The representational concept of measurement provides a rationale for the conclusion that psychophysical methods enable measurement because it admits the numerical representation of intensive magnitudes.

While some advocates of the representational concept of measurement (e.g., [9] and [8]) were critical of the claims of behavioral scientists, others (e.g., [4]) argued that a range of procedures for the measurement of psychological attributes were instances of the measurement of intensive attributes and the representational concept of measurement began to find its way into the behavioral science literature (e.g., [13] and [39]). **S. S. Stevens** ([38] and [39]) took the representational concept further than previous advocates.

Stevens' interpretation of the representational theory was that measurement amounts to numerically modeling 'aspects of the empirical world' [39 p. 23]. The aspects modeled may differ, producing different types of **Scales of Measurement**: modeling a set of discrete, unordered classes gives a *nominal scale*; modeling an ordered attribute gives an *ordinal scale*; modeling differences between levels of an attribute gives an *interval scale*; and, on top of that, modeling ratios between levels of an attribute gives a *ratio scale*. Also, these different types of scales were said to differ with respect to the group of numerical transformations that change the specific numbers used but leave the type of measurement scale unchanged (see **Transformation**). Thus, any one-to-one transformation of the numbers used in a nominal scale map them into a new nominal scale; any order-preserving (i.e., increasing monotonic) transformation of the numbers used in an ordinal scale maps them into a new ordinal scale; any positive linear transformation (i.e., multiplication by a positive constant together with adding or subtracting a constant) maps the numbers used in an interval scale into a new interval scale; and, finally, any positive similarities transformation (i.e., multiplication by a positive constant) maps the numbers used in a ratio scale into a new ratio scale.

Stevens proposed a connection between type of scale and appropriateness of statistical operations. For example, he argued that the computation of means and variances was not permissible given either nominal or ordinal scale measures. He unsuccessfully attempted to justify his prescriptions on the basis of an alleged invariance of the relevant statistics under admissible scale transformations of the measurements involved. His doctrine of permissible statistics had been anticipated by Johnson [13] and it remains a controversial feature of Stevens' theory (see [24] and [44]). Otherwise, Stevens' theory of scales of measurement is still widely accepted within behavioral science.

The identification of these types of scales of measurement with associated classes of admissible transformations was an important contribution to the representational concept and it established a base for further development of this concept by the philosopher, Patrick Suppes, in association with the behavioral scientist, R. Duncan Luce. In a three-volume work, *Foundations of Measurement*, Luce and Suppes, with David Krantz and **Amos Tversky**, brought the representational concept of measurement to an

advanced state, carrying forward Hölder's axiomatic approach to measurement theory and using the conceptual framework of set theory. This approach to measurement involves four steps:

1. An empirical relational system is specified as a nonempty set of entities (objects or attributes of some kind) together with a finite number of distinct qualitative (i.e., nonnumerical) relations between the elements of this set. These elements and relations are the empirical primitives of the system.
2. A set of axioms is stated in terms of the empirical primitives. To the extent that these axioms are testable, they constitute a scientific theory. To the extent that they are supported by data, there is evidence favoring that theory.
3. A numerical relational system is identified such that a set of homomorphic or isomorphic mappings between the empirical and numerical systems can be proved to exist. This proof is referred to as a *representation theorem*.
4. A specification of how the elements of this set of homomorphisms or isomorphisms relate to one another is given, generally by identifying to which class of mathematical functions all transformations of any one element of this set into the other elements belong. A demonstration of this specification is referred to as a *uniqueness theorem* for the scale of measurement involved.

This approach was extended by these authors to the measurement of more than one attribute at a time, for example, to a situation in which the empirical relational system involves an ordering upon the levels of a dependent variable as it relates to two independent variables. As an illustration of this point, consider an ordering upon performances on a set of intellectual tasks (composing a psychological test, say) as related to the abilities of the people and the difficulties of the tasks. The elements of the relevant set are ordered triples (viz., a person's level of ability; a task's level of difficulty; and the level of performance of a person of that ability on a task of that difficulty). The relevant representation theorem proves that the order on the levels of performance satisfies certain conditions (what Krantz, Luce, Suppes & Tversky [16] call *double cancellation*, *solvability* and an *Archimedean condition*) if and only if it is isomorphic to a numerical system in which the elements are triples of real numbers, x , y , and z , such that $x + y = z$ and where

levels of ability map to the first number in each triple, levels of difficulty to the second, levels of performance to the third and order between different levels of performance maps to order between the corresponding values of these third numbers (the *z*s). The relevant uniqueness theorem proves that the mapping from the three attributes (in this case, abilities, difficulties, and performances) to the triples of numbers produce three interval scales of measurement, in Stevens' sense. This particular kind of example of the representational approach to measurement is known as *conjoint measurement* and while it was a relatively new concept within measurement theory, it has proved to be theoretically important. For example, it makes explicit the evidential basis of derived measurement in physical sciences in a way that earlier treatments never did.

Of the three conditions mentioned above (double cancellation, solvability, and the Archimedean condition), only the first is directly testable. As a result, applications of conjoint measurement theory make use of the fact that a finite substructure of any empirical system satisfying these three conditions, will always satisfy a finite hierarchy of cancellation conditions (single cancellation (or independence), double cancellation, triple cancellation, etc.). All of the conditions in this hierarchy are directly testable.

Following the lead of Suppes and Zinnes [40], Luce, Krantz, Suppes & Tversky [21] attempted to reinterpret Stevens' doctrine of permissible statistics using the concept of *meaningfulness*. Relations between the objects or attributes measured are said to be *meaningful* if and only if definable in terms of the primitives of the relevant empirical relational system. This concept of meaningfulness is related to the invariance, under admissible scale transformations of the measurements involved, of the truth (or falsity) of statements about the relation.

The best example of the application of the representational concept of measurement within behavioral science is Luce's [20] investigations of utility in situations involving individual decision making under conditions of risk and uncertainty. Luce's application demonstrates the way in which ideas in representational measurement theory may be combined with experimental research. Within the representational concept, the validity of any proposed method of measurement must always be underwritten by advances in experimental science.

Despite the comprehensive treatment of the representational concept within *Foundations of Measurement*, and also by other authors (e.g., [30] and [31]), the attitude of behavioral scientists to this concept is ambivalent. The range of practices currently accepted within behavioral science as providing interval or ratio scales extends beyond the class demonstrated to be scales of those kinds under the representational concept. These include psychometric methods, which account for the greater part of the practice of measurement in behavioral science. While certain restricted psychometric models may be given a representational interpretation (e.g., Rasch's [33] probabilistic item response model (see [15]), in general, the widespread practice of treating test scores (or components of test scores derived via multivariate techniques like linear factor analysis) as interval scale measures of psychological attributes has no justification under the representational concept of measurement. As a consequence, advocates of established practice within behavioral science have done little more than pay lip service to the representational concept.

The Operational Concept

As a movement in the philosophy of science, operationism was relatively short-lived, but it flourished long enough to gain a foothold within behavioral science, one that has not been dislodged by the philosophical arguments constructed by its many opponents. Operationism was initiated in 1927 by the physicist, P. W. Bridgman [1]. It had a profound influence upon Stevens, who became one of its leading advocates within behavioral science (see [36] and [37]). Operationism was part of a wider movement in philosophy of science, one that tended to think of scientific theories and concepts as reducible to directly observable terms or directly performable operations.

The best-known quotation from Bridgman's writings is his precept that 'in general we mean by any concept nothing more than a set of operations; *the concept is synonymous with the corresponding set of operations*' ([1 p. 5], italics in original). If this is applied to the concept of *measurement*, then *measurement* is nothing more than 'a specified procedure of action which, when followed, yields a number' [17 p. 39].

The operational and representational concepts of measurement are not necessarily incompatible. The genius of Stevens' definition, that 'measurement is the assignment of numerals to objects or events according to rules' [38 p. 667] lies in the fact that it fits both the representational and the operationist concepts of measurement. If the 'rule' for making numerical assignments is understood as one that results in an isomorphism or homomorphism between empirical and numerical relational systems, then Stevens' definition clearly fits the representational concept. On the other hand, if the 'rule' is taken to be any number-generating procedure, then it fits the operational concept. Furthermore, when the components of the relevant empirical relational system are defined operationally, then the representational concept of measurement is given an operational interpretation. (This kind of interpretation was Stevens' [39] preference).

Within the psychometric tradition, Stevens' definition of measurement is widely endorsed (e.g., [19] and [23]). Any specific psychological test may be thought of as providing a precisely specified kind of procedure that yields a number (a test score) for any given person on each occasion of administration. The success of psychometrics is based upon the usefulness of psychological tests in educational and organizational applications and the operational concept of measurement has meant that these applications can be understood using a discourse that embodies a widely accepted concept of measurement. Any psychological test delivers measurements (in the operational sense), but not all such measurements are equally useful. The usefulness of test scores as measurements is generally understood relative to two attributes: *reliability* and *validity* (see **Reliability: Definitions and Estimation; Validity Theory and Applications** [19]). Within this tradition, any measure is thought to be additively composed of two components: a *true* component (defined as the expected value of the measures across an infinite number of hypothetical occasions of testing with person and test held constant) and an *error* component (the difference between the measure and the true component on each occasion). The reliability of a set of measurements provided by a test used within a population of people is understood as the proportion of the variance of the measurements that is *true*. The validity of a test is usually assessed via methods of linear regression (see **Multiple Linear Regression**), for *predictive* validity, and linear **factor analysis**, for *construct* validity, that is,

in terms of the proportion of true variance shared with an observed criterion variable or with a postulated theoretical construct.

The kinds of theoretical constructs postulated include cognitive abilities (such as general ability) and personality traits (such as extraversion). There has been considerable debate within behavioral science as to how realistically such constructs should be interpreted. While the inclusiveness of operationism has obvious advantages, it seems natural to interpret theoretical constructs as if they are real, causally explanatory attributes of people. This raises the issue of the internal structure of such attributes, that is, whether there is evidence that they are quantitative. In this way, thinking about measurement naturally veers away from operationism and toward the traditional concept.

Some behavioral scientists admit that numbers such as test scores, that are thought of as measurements of theoretical psychological attributes, 'generally reflect only ordinal relations between the amounts of the attribute' ([23] p. 446) (see [3] for an extended treatment of this topic and [18] for a discussion in the context of psychophysics). These authors maintain that at present there is no compelling evidence that psychological attributes are quantitative. Despite this, the habit of referring to such numbers as measurements is established in behavioral science and not likely to change. Thus, pressure will continue within behavioral science for a concept that admits as measurement the assignment of numbers to nonquantitative attributes.

Measures of Association

Measures of association quantify the statistical dependence of two or more categorical variables. Many measures of association have been proposed; in this article, we restrict our attention to the ones that are most commonly used. We broadly divide the measures into those suitable for (a) unordered (nominal) categorical variables, and (b) ordered categorical variables. Within these two categories, further subdivisions can be defined. In the case of unordered categorical variables, measures of association can be categorized as (a) measures based on the odds ratio; (b) measures based on Pearson's χ^2 ; and (c) measures of predictive association. In the case of ordered (ordinal) categorical variables, measures of association can be categorized as (a) measures of concordance-discordance and (b) measures based on derived scores.

Measures of Association for Unordered Categorical Variables

Measures Based on the Odds Ratio

The Odds Ratio. The odds that an event will occur are computed by dividing the probability that the event will occur by the probability that the event will not occur (*see Odds and Odds Ratios*) [11]. For example, consider the **contingency table** shown in Table 1, with sex (s) as the row variable and employment status (e) as the column variable.

For males, the odds of being employed equal the probability of being employed divided by the probability of not being employed:

$$odds_{y|m} = \frac{p(y|m)}{1 - p(y|m)} = \frac{p(y|m)}{p(n|m)}$$

Table 1 Employment status of males and females

		Employment status		Total
		Employed (y)	Not employed (n)	
Sex	Male (m)	42	33	75
	Female (f)	40	125	165
	Total	82	58	40

$$= \frac{42/75}{33/75} = \frac{.56}{.44} = 1.27 \quad (1)$$

Similarly, for females:

$$\begin{aligned} odds_{y|f} &= \frac{p(y|f)}{1 - p(y|f)} = \frac{p(y|f)}{p(n|f)} \\ &= \frac{40/165}{125/165} = \frac{.242}{.758} = .319 \end{aligned} \quad (2)$$

These odds are large when employment is likely, and small when it is unlikely. The odds can be interpreted as the number of times that employment occurs for each time it does not. For example, since the odds of employment for males is 1.27, approximately 1.27 males are employed for every unemployed male, or, in round numbers, 5 males are employed for every four males that are unemployed. For females, there is approximately one employed female for every three unemployed females.

The association between sex and employment status can be expressed by the degree to which the two odds differ. This difference can be summarized by the odds ratio (α):

$$\alpha = \frac{odds_{y|f}}{odds_{y|m}} = \frac{p(y|f)/p(n|f)}{p(y|m)/p(n|m)} = \frac{1.27}{.32} = 3.98. \quad (3)$$

This odds ratio indicates that for every one employed female, there are four employed males. Although not necessary, it is customary to place the larger of the two odds in the numerator [11]. Also note that the odds ratio can be expressed as the cross-product of the cell frequencies of the contingency table:

$$\begin{aligned} \alpha &= \frac{p(y|m)p(n|f)}{p(y|f)p(n|m)} = \frac{(42/75)(125/165)}{(40/165)(33/75)} \\ &= \frac{(42)(125)}{(40)(33)} = 3.98. \end{aligned} \quad (4)$$

Thus, the odds ratio is also known as the cross-product ratio.

The odds ratio can be applied to larger than 2×2 **contingency tables**, although its interpretation becomes difficult when there are more than two columns. However, when the number of rows is greater than two, interpreting the odds ratio

2 Measures of Association

Table 2 Employment status within three regions

		Employment status		Total
		Employed (y)	Not employed (n)	
Region	West (w)	90	10	100
	South (s)	80	20	100
	East (e)	99	1	100
	Total	269	31	300

is relatively straightforward. For example, consider Table 2.

Within any of the three regions, we can determine the odds that someone in that region will be employed. This is accomplished by dividing the probability for those in a given region being employed by the probability for those in the same region not being employed. Thus, for the west, the odds of being employed are $(90/100)/(10/100) = 9$. For the south, the odds of being employed are $(80/100)/(20/100) = 4$. For the east, the odds of being employed are $(99/100)/(1/100) = 99$. From these three odds, we can compute the following three odds ratios: (a) the odds ratio of someone in the east being employed versus someone in west being employed ($\alpha = 99/9 = 11$); (b) the odds ratio of someone in the east being employed versus someone in the south being employed ($\alpha = 99/4 = 24.75$); and (c) the odds ratio of someone in the west being employed versus someone in the south being employed ($\alpha = 9/4 = 2.25$). Thus, the odds of someone in the east being employed are 11 times larger than the odds of someone in the west being employed, and 24.75 times larger than someone in the south. The odds of someone in the west being employed are 2.25 times larger than the odds of someone in the south being employed. The odds ratio is invariant under interchanges of rows and columns; switching only rows or columns changes α to $1/\alpha$ [11].

Odds ratios are not symmetric around one: An odds ratio larger than one by a given amount indicates a smaller effect than an odds ratio smaller than one by the same amount [11]. While the magnitude of an odds ratio less than one is restricted to the range between zero and one, odds ratios greater than one are not restricted, allowing the ratio to potentially take on any value. If the natural logarithm ($\ln$) of the odds ratio is taken, the

odds ratio is symmetric above and below one, with $\ln(1) = 0$. For example, to take the 2×2 example above, the odds ratio of a male being employed, compared to a female, was 3.98. If we reverse that and take the odds ratio of a female being employed compared to a male, it is $.32/1.27 = .25$. These ratios are clearly not symmetric about 1.00. However, $\ln(3.98) = 1.38$ and $\ln(.25) = -1.38$, and these ratios are symmetric.

Yule's Q Coefficient of Association. Both α and $\ln(\alpha)$ range from $-\infty$ to $+\infty$. In order to restrict the odds ratio within the interval -1 to $+1$, Yule introduced the coefficient of association, Q , for 2×2 tables. Its definition is [12]:

$$Q = \frac{n_{11}n_{22} - n_{12}n_{21}}{n_{11}n_{22} + n_{12}n_{21}} = \frac{\alpha - 1}{\alpha + 1}. \quad (5)$$

Therefore, if odds ratio (α) expressing the relationship between sex and employment is 3.98,

$$\begin{aligned} Q &= \frac{(42)(125) - (33)(40)}{(42)(125) + (33)(40)} \\ &= \frac{3.98 - 1}{3.98 + 1} = .59. \end{aligned} \quad (6)$$

Yule's Q is algebraically equal to the 2×2 Goodman-Kruskal γ coefficient (described below), and, thus, measures the degree of concordance or discordance between two variables.

Yule's Coefficient of Colligation. As an alternative to Q , Yule proposed the *coefficient of colligation* [12]:

$$\hat{Y} = \frac{\sqrt{n_{11}n_{22}} - \sqrt{n_{12}n_{21}}}{\sqrt{n_{11}n_{22}} + \sqrt{n_{12}n_{21}}} = \frac{\sqrt{\alpha} - 1}{\sqrt{\alpha} + 1}. \quad (7)$$

The coefficient of colligation between sex and employment is

$$\begin{aligned} \hat{Y} &= \frac{\sqrt{(42)(125)} - \sqrt{(33)(40)}}{\sqrt{(42)(125)} + \sqrt{(33)(40)}} \\ &= \frac{\sqrt{3.98} - 1}{\sqrt{3.98} + 1} = .33. \end{aligned} \quad (8)$$

The coefficient of colligation has a different interpretation than the coefficient of association, and is interpreted as a **Pearson product-moment correlation coefficient r** (see below), but is not algebraically equivalent to one.

Both Q and $\hat{Y}$ are symmetric measures of association, and are invariant under changes in the ordering of rows and columns.

Measures Based on Pearson's χ^2

Pearson's Chi-square Goodness-of-fit Test Statistic. (See **Goodness of Fit for Categorical Variables**),

$$\chi^2 = \sum_i \sum_j \frac{(n_{ij} - \hat{n}_{ij})^2}{n_{ij}}, \quad (9)$$

where $\hat{n}_{ij}$ is the expected frequency in cell ij , and can be usefully transformed into several measures of association [1].

The Phi Coefficient. The *phi coefficient* is defined as [5]:

$$\Phi = \sqrt{\frac{\chi^2}{N}}. \quad (10)$$

For sex and employment,

$$\Phi = \sqrt{\frac{23.12}{240}} = 0.31. \quad (11)$$

The phi coefficient can vary between 0 and 1, and is algebraically equivalent to $|r|$. However, the lower and upper limits of Φ in a 2×2 table are dependent on two conditions. In order for Φ to equal -1 or $+1$, (a) $(n_{11} + n_{12}) = (n_{21} + n_{22})$, and (b) $(n_{11} + n_{21}) = (n_{12} + n_{22})$.

The Pearson Product-moment Correlation Coefficient. The general formula for the *Pearson product-moment correlation coefficient* is

$$r = \frac{\sum_i (X_i - \bar{X})(Y_i - \bar{Y})}{N s_x s_y}, \quad (12)$$

where X and Y are two continuous, interval-level variables. The categories of a dichotomous variable can be coded 0 and 1, and used in the formula for r . In a 2×2 contingency table, the calculations reduce to [10]:

$$r = \frac{n_{11}n_{22} - n_{12}n_{21}}{\sqrt{n_{1+}n_{2+}n_{+1}n_{+2}}}. \quad (13)$$

For sex and employment, $r = \{(42)(125) - (33)(40) / \sqrt{[(75)(165)(82)(158)]}\} = .31$.

A symmetric measure of association also invariant to row and column order, r varies between -1 to $+1$. From the formula, it is apparent that $r = 1$ if $n_{12} = n_{21} = 0$, and $r = -1$ if $n_{11} = n_{22} = 0$. In a standardized 2×2 table, where each marginal probability = .5, $r = \hat{Y}$; otherwise $|r| < |\hat{Y}|$ except when the variables are independent or completely related.

Cramèr's Phi Coefficient. *Cramèr's phi coefficient* V is an extension of the phi coefficient to contingency tables that are larger than 2×2 [10]:

$$V = \sqrt{\frac{\chi^2}{N(k-1)}}, \quad (14)$$

where k is the number of rows or columns, whichever is smaller. Cramèr's phi coefficient is based on the fact that the maximum value chi-square can attain for a set of data is $N(k-1)$; thus, when chi-square is equal to $N(k-1)$, $V = 1$.

Cramèr's phi coefficient and the phi coefficient are equivalent for 2×2 tables. When applied to a 4×2 table for region and employment,

$$V = \sqrt{\frac{204.38}{500(2-1)}} = .64. \quad (15)$$

The Contingency Coefficient. Another variation of the phi coefficient, the *contingency coefficient* $\hat{C}$ is a measure of association that can be computed for an $r \times c$ of any size [9]:

$$\hat{C} = \sqrt{\frac{\chi^2}{\chi^2 + N}}. \quad (16)$$

Applied to the 4×2 table between region and employment,

$$\hat{C} = \sqrt{\frac{204.38}{204.38 + 500}} = .54. \quad (17)$$

Note that, unlike V , $\hat{C}$ does not equal Φ computed for 2×2 tables. For example, while V and Φ both equal .31 for the association between sex and employment,

$$\hat{C} = \sqrt{\frac{23.12}{23.12 + 240}} = .29. \quad (18)$$

4 Measures of Association

The contingency coefficient can never equal 1, since N cannot equal 0. Thus, the range of $\hat{C}$ is $0 \leq \hat{C} < +1$. Another limitation of $\hat{C}$ is its dependence on the number of rows and columns in an $r \times c$ table. The upper limit of $\hat{C}$ is

$$\hat{C}_{\max} = \sqrt{\frac{k-1}{k}}. \quad (19)$$

Therefore, for 2×2 tables, $\hat{C}$ can never exceed .71; that is, $\hat{C}_{\max} = \sqrt{[(2-1)/2]} = .71$. In fact, $\hat{C}$ will always be less than 1, even when the association between two variables is perfect [9]. In addition, values of $\hat{C}$ for two tables can only be compared when the tables have the same number of rows and the same number of columns. To counter these limitations, an adjustment can be applied to $\hat{C}$:

$$\hat{C}_{\text{adj}} = \frac{\hat{C}}{\hat{C}_{\max}}. \quad (20)$$

Thus, when the association between two variables is 1.00, $\hat{C}_{\text{adj}}$ will reflect this. For region and employment, $\hat{C}_{\text{adj}} = .54/.71 = .76$, and for sex and employment, $\hat{C}_{\text{adj}} = .29/.71 = .41$.

Measures of Predictive Association

Another class of measures of association for nominal variables is measures of prediction analogous in concept to the multiple correlation coefficient in regression analysis [12]. When there is an association between two nominal variables X and Y , then knowledge about X allows one to obtain knowledge about Y , more knowledge than would have been available without X . Let Δ_Y be the dispersion of Y and $\Delta_{Y.X}$ be the conditional dispersion of Y given X . A measure of prediction

$$\phi_{Y.X} = 1 - \frac{\Delta_{Y.X}}{\Delta_Y} \quad (21)$$

compares the conditional dispersion of Y given X to the unconditional dispersion of Y , similar to how the multiple correlation coefficient compares the conditional variance of the dependent variable to its unconditional variance [1]. When $\phi_{Y.X} = 0$, X and Y are independently distributed; when $\phi_{Y.X} = 1$, X is a perfect predictor of Y .

We describe four measures that operationalize the idea underlying $\phi_{Y.X} = 0$.

The first measure is the *asymmetric lambda coefficient* of Goodman and Kruskal [7]:

$$\begin{aligned} \lambda(Y = c|X = r) &= \frac{\sum_i \max_j p_{ij} - \max_j p_{+j}}{1 - \max_j p_{+j}}, \\ \lambda(X = r|Y = c) &= \frac{\sum_j \max_i p_{ij} - \max_i p_{+i}}{1 - \max_i p_{+i}}. \end{aligned} \quad (22)$$

The second is the *symmetric lambda coefficient* (λ) of Goodman and Kruskal [7]:

$$\lambda = \frac{\sum_i \max_j p_{ij} + \sum_j \max_i p_{ij} - \max_j p_{+j} - \max_i p_{+i}}{2 - \max_j p_{+j} - \max_i p_{+i}}. \quad (23)$$

The third is the *asymmetric uncertainty coefficient* of Theil [4]:

$$\begin{aligned} U(Y = c|X = r) &= \frac{\left(-\sum_i (p_{i+}) \ln(p_{i+}) \right) + \left(-\sum_j (p_{+j}) \ln(p_{+j}) \right) - \left(-\sum_i \sum_j (p_{ij}) \ln(p_{ij}) \right)}{-\sum_j (p_{+j}) \ln(p_{+j})}, \\ U(X = r|Y = c) &= \frac{\left(-\sum_i (p_{i+}) \ln(p_{i+}) \right) + \left(-\sum_j (p_{+j}) \ln(p_{+j}) \right) - \left(-\sum_i \sum_j (p_{ij}) \ln(p_{ij}) \right)}{-\sum_i (p_{i+}) \ln(p_{i+})}. \end{aligned} \quad (24)$$

The fourth measure of predictive association is U , Theil's *symmetric uncertainty coefficient* [4]:

$$U = \frac{2 \left[\left(-\sum_i (p_{i+}) \ln(p_{i+}) \right) + \left(-\sum_j (p_{+j}) \ln(p_{+j}) \right) - \left(-\sum_i \sum_j (p_{ij}) \ln(p_{ij}) \right) \right]}{\left(-\sum_i (p_{i+}) \ln(p_{i+}) \right) + \left(-\sum_j (p_{+j}) \ln(p_{+j}) \right)}. \quad (25)$$

We use the contingency table shown in Table 3 to illustrate, in turn, the computation of the four measures of predictive association.

The first measure, asymmetric $\lambda(Y|X)$, is interpreted as the relative decrease in the probability of incorrectly predicting the column variable Y between not knowing X and knowing X . As such, lambda can also be interpreted as a proportional reduction in variation measure – how much of the variance in one variable is accounted for by the other? In the equation for $\lambda(Y|X)$, $1 - \max_j p_{+j}$ is the minimum probability of error from the prediction that Y is a function of X , and $1 - \max_i p_{i+}$ is the minimum probability of error from a prediction that Y is a constant over X . For the data we obtain:

$$\begin{aligned} \lambda(Y|X) &= \frac{((49 + 44 + 63)/432) - (119/432)}{1 - (119/432)} \\ &= \frac{.36 - .28}{1 - .28} = .11. \end{aligned} \quad (26)$$

Thus, there is an 11% improvement in predicting the column variable Y given the knowledge of the row variable X . Asymmetric λ has the range $0 \leq \lambda(Y|X) \leq 1$.

Table 3 The computation of the four measures of predictive association

	Y_1	Y_2	Y_3	Y_4	Total
X_1	28	32	49	36	145
X_2	44	21	17	12	94
X_3	46	31	53	63	193
Total	118	84	119	111	

In general, $\lambda(Y|X) \neq \lambda(X|Y)$; $\lambda(X|Y)$ is the relative decrease in the probability of incorrectly predicting the row variable X between not knowing Y and knowing Y – hence, the term ‘asymmetric’. For these data,

$$\begin{aligned} \lambda(X|Y) &= \frac{((46 + 32 + 53 + 63)/432) - (193/432)}{1 - (193/432)} \\ &= \frac{.45 - .44}{1 - .44} = .02. \end{aligned} \quad (27)$$

Symmetric λ is the average of the two asymmetric lambdas and has the range $0 \leq \lambda \leq 1$. For our example,

$$\lambda = \frac{.36 + .45 - .28 - .44}{2 - .28 - .44} = \frac{.09}{1.28} = .07. \quad (28)$$

Theil’s asymmetric uncertainty coefficient, $U(Y|X)$, is the proportion of uncertainty in the column variable Y that is explained by the row variable X , or, alternatively, $U(X|Y)$ is the proportion of uncertainty in the row variable X that is explained by the column variable Y . The asymmetric uncertainty coefficient has the range $0 \leq U(Y|X) \leq 1$. For $U(Y|X)$, we obtain for these data:

$$U(Y|X) = \frac{(1.06) + (1.38) - (2.40)}{1.38} = .03, \quad (29)$$

and for $U(X|Y)$,

$$U(X|Y) = \frac{(1.06) + (1.38) - (2.40)}{1.06} = .04. \quad (30)$$

The symmetric U is computed as

$$U = \frac{2[(1.06) + (1.38) - (2.40)]}{(1.06) + (1.38)} = .03. \quad (31)$$

Both the asymmetric and symmetric uncertainty coefficients have the range $0 \leq U \leq 1$.

The quantities in the numerators of the equations for the asymmetric lambda and uncertainty coefficients are interpreted as measures of variation for nominal responses: In the case of lambda coefficients, the variation measure is called the *Gini concentration*, and the variation measure used in the uncertainty coefficients is called the *entropy* [12]. More specifically, in $\lambda(Y|X)$, the numerator represents the variance of the Y or column variable:

$$V(Y) = \sum_i \max_j p_{ij} - \max_j p_{+j}, \quad (32)$$

6 Measures of Association

and in $\lambda(X|Y)$, the numerator represents the variance of the X or row variable:

$$V(X) = \sum_j \max_i p_{ij} - \max_i p_{i+}. \quad (33)$$

Analogously, the numerator of $U(Y|X)$ is the variance of Y ,

$$\begin{aligned} V(Y) = & \left(- \sum_i (p_{i+}) \ln(p_{i+}) \right) \\ & + \left(- \sum_j (p_{+j}) \ln(p_{+j}) \right) \\ & - \left(- \sum_i \sum_j (p_{ij}) \ln(p_{ij}) \right); \end{aligned} \quad (34)$$

and the numerator of $U(X|Y)$ is the variance of X ,

$$\begin{aligned} V(X) = & \left(- \sum_i (p_{i+}) \ln(p_{i+}) \right) \\ & + \left(- \sum_j (p_{+j}) \ln(p_{+j}) \right) \\ & - \left(- \sum_i \sum_j (p_{ij}) \ln(p_{ij}) \right). \end{aligned} \quad (35)$$

However, in these measures, there is a positive relationship between the number of categories and the magnitude of the variation, thus introducing ambiguity in evaluating both the variance of the variables and their relationship.

Measures of Association for Ordered Categorical Variables

Measures of Concordance/Discordance

A pair of observations is *concordant* if the observation that ranks higher on X also ranks higher on Y . A pair of observations is *discordant* if the observation that ranks higher on X ranks lower on Y (see **Nonparametric Correlation (tau)**). The number of concordant pairs is

$$C = \sum_{i < i'} \sum_{j < j'} n_{ij} n_{i'j'}, \quad (36)$$

where the first summation is over all rows $i < i'$, and the second summation is over all pairs of columns $j < j'$. The number of discordant pairs is

$$D = \sum_{i < i'} \sum_{j > j'} n_{ij} n_{i'j'}, \quad (37)$$

where the first summation is over all rows $i < i'$, and the second summation is over all columns $j > j'$.

To illustrate the calculation of C and D , consider the 3×3 contingency table shown in Table 4 cross-classifying income with education.

In this table, the number of concordant pairs is

$$\begin{aligned} C = & 302(331 + 250 + 155 + 185) \\ & + 105(250 + 185) + 409(155 + 185) \\ & + 331(185) = 524\,112. \end{aligned} \quad (38)$$

Note that the process of identifying concordant pairs amounts to taking each cell frequency (e.g., 302) in turn, and multiplying that frequency by each of the cell frequencies 'southeast' of it (e.g., 331, 250, 155, 185).

The number of discordant pairs is

Table 4 Income for three levels of education

		Income				Proportion
		Low	Medium	High	Total	
Education	LT than high school	302	105	23	430	0.243
	High school	409	331	250	990	0.557
	GT than high school	15	155	185	355	0.200
	Total	726	591	458	1775	1.00
	Proportion	0.409	0.333	0.258	1.00	

$$\begin{aligned}
D &= 23(409 + 331 + 15 + 155) \\
&+ 105(409 + 15) + 250(15 + 155) \\
&+ 331(15) = 112\,915. \quad (39)
\end{aligned}$$

Discordant pairs can readily be identified by taking each cell frequency (e.g., 23) in turn, and multiplying that cell frequencies by each of the cell frequencies ‘southwest’ of it (e.g., 409, 331, 15, 155).

Let $n_{i+} = \sum_j n_{ij}$ and $n_{+j} = \sum_i n_{ij}$. We can express the total number of pairs of observations as

$$\frac{n(n-1)}{2} = C + D + T_X + T_Y - T_{XY}, \quad (40)$$

where $T_X = \sum_i n_i(n_{i+} - 1)/2$ is the number of pairs tied on the row variable X , $T_Y = \sum_j n_j(n_{+j} - 1)/2$ is the number of pairs tied on the column variable Y , and $T_{XY} = \sum_i \sum_j n_{ij}(n_{ij} - 1)/2$ is the number of pairs from a common cell (tied on X and Y). In this formula for $n(n-1)/2$, T_{XY} is subtracted because pairs tied on both X and Y have been counted twice, once in T_X and once in T_Y . Therefore,

$$\begin{aligned}
T_X &= \frac{(430 \times 429) + (990 \times 989) + (355 \times 354)}{2} \\
&= 644\,625 \\
T_Y &= \frac{(726 \times 725) + (591 \times 590) + (458 \times 457)}{2} \\
&= 542\,173 \\
T_{XY} &= \frac{(302 \times 301) + (105 \times 104) + \dots + (185 \times 184)}{2} = 249\,400 \\
\frac{n(n-1)}{2} &= (524\,112) + (112\,915) + (644\,625) \\
&\quad + (542\,173) - (249\,400) \\
&= 1\,574\,425. \quad (41)
\end{aligned}$$

Kendall’s tau Statistics. Several measures of concordance/discordance are based on the difference $C - D$. Kendall’s three *tau* (τ) statistics are among the most well known of these, and can be applied to $r \times c$ contingency tables with $r \geq 2$ and $c \geq 2$. The row and column variables do not have to have the

same number of categories. The tau statistics have the range $-1 \leq 0 \leq +1$.

The three tau statistics are [6]:

$$\begin{aligned}
\tau_a &= \frac{2(C - D)}{N(N - 1)} \\
\tau_b &= \frac{(C - D)}{\sqrt{[(C + D + T_Y - T_{XY})(C + D + T_X - T_{XY})]}} \\
\tau_c &= \frac{2m(C - D)}{N^2(m - 1)}, \quad (42)
\end{aligned}$$

where m = the number of rows or column, whichever is smaller. For our data, the tau statistics are equal to

$$\begin{aligned}
\tau_a &= \frac{2(524\,112 - 112\,915)}{1775(1775 - 1)} = .26 \\
\tau_b &= \frac{(524\,112 - 112\,915)}{\sqrt{[(524\,112 + 112\,915 + 542\,173 - 249\,900) \\
&\quad (524\,112 + 112\,915 + 644\,625 - 249\,900)]}} \\
&= .42 \\
\tau_c &= \frac{3 \times 2(524\,112 - 112\,915)}{1775^2(3 - 1)} = .39. \quad (43)
\end{aligned}$$

One note of qualification is that tau-a assumes there are no tied observations; thus, strictly speaking, it is not applicable to contingency tables. It is generally more useful as a measure of rank correlation. For 2×2 tables, τ_b simplifies to the Pearson product-moment correlation obtained by assigning any scores to the rows and columns consistent with their orderings.

Goodman and Kruskal’s Gamma. Goodman and Kruskal suggested yet another measure, *gamma* (γ) based on $C - D$ [7]:

$$\gamma = \frac{C - D}{C + D}. \quad (44)$$

For our example data, $\gamma = (524\,112 - 112\,915)/(524\,112 + 112\,915) = .65$. Gamma has the range $-1 \leq 0 \leq +1$, equal to $+1$ when the data are concentrated in the upper-left to lower-right diagonal, and equal to -1 for the converse pattern. Although γ does equal zero when the two variables are independent, two variables can be completely dependent and still have a value of γ less than unity. For 2×2 tables, γ is equal to Yule’s Q .

8 Measures of Association

Somers' $\hat{d}$. Gamma and the tau statistics are symmetric measures. Somers proposed an alternative asymmetric measure [7]:

$$\hat{d}(Y = c|X = r) = \frac{(C - D)}{\left[\frac{n(n-1)}{2} - T_X \right]}, \quad (45)$$

for predicting the column variable Y from the row variable X , or

$$\hat{d}(X = r|Y = c) = \frac{(C - D)}{\left[\frac{n(n-1)}{2} - T_Y \right]}, \quad (46)$$

for predicting X from Y . For these data, we compute

$$\begin{aligned} \hat{d}(Y|X) &= \frac{(524\,112 - 112\,915)}{(1\,574\,425 - 644\,625)} = .44 \\ \hat{d}(X|Y) &= \frac{(524\,112 - 112\,915)}{(1\,574\,425 - 542\,173)} = .40. \end{aligned} \quad (47)$$

Somers' $\hat{d}$ can be interpreted as the difference between the proportions of concordant and discordant pairs, using only those pairs that are untied on the predictor variable. For 2×2 tables, Somers' $\hat{d}$ simplifies to the difference of proportions $n_{11}/n_{1+} - n_{21}/n_{2+}$ (for $\hat{d}(Y|X)$), or to the difference of proportions $n_{11}/n_{+1} - n_{12}/n_{+2}$ (for $\hat{d}(X|Y)$). Yet another interpretation of Somers' d is as a least-squares regression slope [4]. To see this more clearly, we rewrite $\hat{d}(Y|X)$ as $\hat{d}_{YX}$ and $\hat{d}(X|Y)$ as $\hat{d}_{XY}$, we note that

$$\begin{aligned} \tau_b^2 &= \hat{d}_{YX}\hat{d}_{XY} \\ .42^2 &= (.44)(.40). \end{aligned} \quad (48)$$

Recalling in least-squares regression that

$$r^2 = b_{YX}b_{XY}, \quad (49)$$

we see the analogy between τ_b^2 and r^2 as coefficients of determination, and $\hat{d}_{YX}$, $\hat{d}_{XY}$ and b_{YX} , b_{XY} as regression coefficients. In addition, we note, as is true for γ , Somers' $\hat{d}$ equals zero when the two variables are independent, but is not necessarily equal to unity when the two variables are completely dependent.

Measures Based on Derived Scores

Some methods for measuring the association between ordinal variables require assigning scores to the levels of the ordinal variables (see **Ordinal Regression**

Models). When a contingency table is involved, scale values are assigned to row and column categories, the data are treated as a grouped frequency distribution, and the Pearson product-moment correlation is computed.

Specifically, let x_i and y_j be the values assigned to the rows and columns. The Pearson product-moment correlation for grouped data is then

$$r = \frac{CP_{XY}}{\sqrt{SS_X SS_Y}}, \quad (50)$$

where CP_{XY} is the sum of cross products,

$$CP_{XY} = \sum_{i,j} x_i y_j n_{ij} - \frac{\left(\sum_i x_i n_{i+} \right) \left(\sum_j y_j n_{+j} \right)}{n_{++}}, \quad (51)$$

and SS_X and SS_Y are the sums of squares,

$$\begin{aligned} SS_X &= \sum_i x_i^2 n_{i+} - \frac{\left(\sum_i x_i n_{i+} \right)^2}{n_{++}}, \\ SS_Y &= \sum_j y_j^2 n_{+j} - \frac{\left(\sum_j y_j n_{+j} \right)^2}{n_{++}}. \end{aligned} \quad (52)$$

Therefore, if for our 3×3 contingency table for income and education, we assign the values, '1', '2', and '3' to the three levels of each variable, we have

$$\begin{aligned} CP_{XY} &= 6863 - \frac{(3475)(3282)}{1775} = 437.68, \\ SS_X &= 7585 - \frac{(3475)^2}{1775} = 781.83, \\ SS_Y &= 7212 - \frac{(3282)^2}{1775} = 1143.54, \\ r &= \frac{437.68}{\sqrt{(781.83)(1143.54)}} = .46. \end{aligned} \quad (53)$$

The value of $r = .46$ is also known as the *Spearman rank correlation coefficient* r_s , sometimes referred to as **Spearman's rho** [8]. The Spearman rank correlation coefficient can also be computed by using:

$$r_s = \frac{6 \sum d^2}{n(n^2 - 1)}, \quad (54)$$

where d is the difference in the rank scores between X and Y . Computed by using this formula,

$$r_s = \frac{6(20706)^2}{1775(1775^2 - 1)} = .46. \quad (55)$$

Instead of using the rank scores of '1', '2', and '3' directly, we can use *ridit scores* [2]. Ridit scores are cumulative probabilities; each ridit score represents the proportion of observations below category j plus half the proportion within j . We illustrate the calculation of ridit scores using the income and education contingency table. Beneath each marginal total is the proportion of observations in the row or column. The ridit score for the low income category is $.5(.409) = .205$; for medium income, $.409 + .5(.333) = .576$; and for high income, the ridit score is $.409 + .333 + .5(.258) = .871$. The ridit scores for less than high school education is $.5(.243) = .122$; for high school education, $.243 + .5(.557) = .522$; and for greater than high school education, the ridit score is $.243 + .557 + .5(.200) = .900$. Applying the Pearson product-moment correlation formula to the ridit scores, we obtain $r_s = .47$.

Scores for the ordered levels of categorical variable can also be derived by assuming that the variables have an underlying bivariate normal distribution. *Normal scores* computed from 2×2 contingency tables produce the **tetrachoric correlation**; when computed from larger tables, the correlation is known as the **polychoric correlation** [3]. The Tetrachoric/polychoric correlation is the **maximum likelihood estimate** of the Pearson product-moment

correlation between the bivariate normally distributed variables. The polychoric correlation between education and income is .57.

Median

The median is a measure of central tendency (or location). It is defined as the point in an ordered set of data such that 50% of scores fall below it and 50% above it. The median is thus the 50th **percentile** and the second **quartile** (Q_2).

To find the median, we first place a set of scores in order of their size and then locate the value that is in the middle of the ordered set. This is straightforward when there is an odd number of scores in the set, as the median will be the member of the set that has as many scores below it as above it. For example, for the set of seven numbers 1, 3, 4, 5, 7, 9, and 11, 5 is the median and there are three numbers below it and three above it.

Formally, when the number of scores in the set (N) is odd, the median is the $[(N + 1)/2]$ th value in the set. Accordingly, for the above-mentioned data, the median is the 4th in the ordered set, which is, as before, 5.

When there is an even number of values in the set, the median is taken to be the mean of the $(N/2)$ th and the $[N/2 + 1]$ th values. Suppose that the above-mentioned set had the value 15 added to it so that it now contained eight numbers, then the median would be the mean of the 4th and 5th scores in the ordered set, that is, the mean of 7 and 9, which is 8.

When data are presented as frequencies within ranges rather than as individual values, it is possible to estimate the value of the median using interpolation.

Suppose that we want to find the median age of a set of 100 young people from the data presented in Table 1.

It can be seen quite easily that the median is in the age range 10 to 14 years. However, as we have no

other information, we are forced to assume that the ages of the 35 people in that age range are evenly distributed across it. Given that assumption, we can see that the median age is at the beginning of that range, as the 48th percentile (from the cumulative frequency) is in the age range 5 to 9.

One equation for calculating an approximate value for the median in such a situation is

$$\text{Median} = L_m + \left[C_m \times \left\{ \frac{\left(\frac{1}{2} \times N \right) - F_{m-1}}{F_m} \right\} \right], \quad (1)$$

where L_m is the lowest value in the range that contains the median, C_m is the width of the range that contains the median, F_{m-1} is the cumulative frequency below the range that contains the median, F_m is the frequency within the range that contains the median, and N is the total sample size.

Therefore, in the tabulated data, the median would be found from

$$10 + \left[5 \times \left\{ \frac{\left(\frac{1}{2} \times 100 \right) - 48}{35} \right\} \right] = 10.29. \quad (2)$$

An advantage of the median is that it is not affected by extreme scores; for example, if instead of adding 15 to the original 7-item set above, we added 100, then the median would still be 8. However, as with the mean, with discrete distributions, a data set containing an even number of values can produce a median, which is not possible, for example, if it was found that the median number of people in a family is 3.5.

The median is an important robust measure of location for **exploratory data analysis** (EDA) and is a key element of a box plot [1].

Median Absolute Deviation

The median deviation (M.A.D.) is a robust measure of scale, usually defined as

$$\text{M.A.D.} = \text{median}|X_i - \text{median}|. \quad (1)$$

We can see that the M.A.D. is simply the average distance of observations from the median of the distribution.

For a normally distributed variable, the M.A.D. is equal to 0.6745 times the standard deviation (SD) and 0.8453 times the **average deviation** (AD). (For distributions of the same shape, these estimators are linearly related.) The M.A.D. becomes increasingly

smaller than the standard deviation for distributions with thicker tails.

The major advantage of the M.A.D. over the AD, both of which are more efficient than the SD for even slightly heavier than normal distributions, is that the M.A.D. is more robust. This led Mosteller and Tukey [1] to class the M.A.D. and the interquartile range as robust measures of scale, as ‘the best of an inferior lot.’

Median Test

This test for the equivalence of the medians of $k \geq 2$ sampled populations was introduced by Mood in 1950 [3]. The null hypothesis is that the k populations have the same median and the alternative is that at least two of the populations have differing medians.

The test requires random samples to be taken independently from the k populations and is based on the following assumption. If all the populations have a common median, then the probability that a randomly sampled value will lie above the grand sample median will be the same for each of the populations [1].

To carry out the test, one first finds the grand sample median, the median of the combined samples. Then, the sample data are reduced to a two-way table of frequencies. The k columns of the table correspond to the k samples and the two rows correspond to sample observations falling above and at or below the grand sample median.

As an example, [2] reports the results of an experiment on the impact of caffeine on finger tapping rates. Volunteers were trained at the task and then randomized to receive a drink containing 0 mg, 100 mg, or 200 mg caffeine. Two hours after

Table 1 Caffeine and finger tapping rates

Dosage (mg)	Tapping speeds
0	242, 245, 244, 248, 247, 248, 242, 244, 246, 242
100	248, 246, 245, 247, 248, 250, 247, 246, 243, 244
200	246, 248, 250, 252, 248, 250, 246, 248, 245, 250

Table 2 Distribution of tapping speeds about grand median

	0 mg	100 mg	200 mg
Above grand median	3	5	7
Below grand median	7	5	3

consuming the drink, the rates of tapping, given in Table 1, were recorded.

The grand sample median for these data is a value between 246 and 247. By custom, it is taken to be midway, at 246.5. Table 2 describes how the 30 tapping speeds, 10 in each caffeine dosage group, are distributed about this grand median.

Where, as here, $k > 2$, the test is completed as a chi-squared test of independence in a two-way table. The resulting P value is 0.2019. As the expected cell frequencies are small in this example, the result is only approximate.

Where $k = 2$, Fisher’s exact test (*see Exact Methods for Categorical Data*) can be used to test for independence. As the name implies, the resulting P value is exact rather than approximate.

Mediation

Mediation presumes a causal chain. As seen in Figure 1, the variable X causes M (path a) and M in turn causes Y (path b). The variable M is said to *mediate* the X to Y relationship. *Complete mediation* is defined as the case in which variable X no longer affects Y after M has been controlled and so path c' is zero. *Partial mediation* is defined as the case in which the effect of X on Y is reduced when M is introduced, but c' is not equal to zero. The path from X to Y without M being controlled for is designated here as c . A mediator is sometimes called an *intervening variable* and is said to *elaborate* a relationship.

Given the model in the Figure 1, there are, according to Baron and Kenny [1], four steps in a mediational analysis. They are as follows.

- Step 1:* Show that X predicts the Y . Use Y as the criterion variable in a regression equation and X as a predictor. This step establishes that X is effective and that there is some effect that may be mediated.
- Step 2:* Show that X predicts the mediator, M . Use M as the criterion variable in a regression equation and X as a predictor (estimate and test path a in Figure 1). This step essentially involves treating the mediator as if it were an outcome variable.
- Step 3:* Show that the mediator, M , predicts Y . Use Y as the criterion variable in a regression equation and X and M as predictors (estimate and test path b in the Figure 1). It

Figure 1 Basic mediational model: The variable M mediates the X to Y relationship

is insufficient just to correlate the mediator with Y because the mediator and Y may be both caused by X . The effect of X must be controlled in establishing the effect of the mediator on Y .

- Step 4:* To establish that M *completely* mediates the $X - Y$ relationship, the effect of X on Y controlling for M should be zero (estimate and test path c' in Figure 1). The effects in both steps 3 and 4 are estimated in the same regression equation where Y is the criterion and X and M are the predictors.

If all of these steps are met, then the data are consistent with the hypothesis that M completely mediates the $X - Y$ relationship. Partial mediation is demonstrated by meeting all but Step 4. It can sometimes happen that Step 1 fails because of a suppressor effect (c' and ab have different signs). Hence, the essential steps in testing for mediation are 2 and 3.

Meeting these steps does not, however, conclusively prove the mediation hypothesis because there are other models that are consistent with the data. So for instance, if one makes the mediator the outcome and vice versa, the results may look like 'mediation'. Design (e.g., measuring M before Y) and measurement (e.g., not using self-report to measure M and Y) features can strengthen the confidence that the model in the Figure 1 is correct.

If both steps 2 and 3 are met, then necessarily the effect of X on Y is reduced when M is introduced. Theoretically, the amount of reduction, also called the *indirect effect*, or $c - c'$ equals ab . So, the amount of reduction in the effect of X on Y is ab and not the change in an inferential statistic such as, F , p , or variance explained. Mediation or the indirect effect equals, in principle, the reduction in the effect of X to Y when the mediator is introduced. The fundamental equation in mediational analysis is

$$\text{Total effect} = \text{Direct Effect} + \text{Indirect Effect} \quad (1)$$

or mathematically

$$c = c' + ab \quad (2)$$

When **multiple linear regression** is used, ab exactly equals $c - c'$, regardless of whether standardized or unstandardized coefficients are used (see **Standardized Regression Coefficients**). However,

for **logistic regression**, multilevel modeling (*see Generalized Linear Mixed Models*), and **structural equation modeling**, ab only approximately equals $c - c'$. In such cases, it is probably advisable to estimate c by $ab + c'$ instead of estimating it directly.

There are two major ways to evaluate the null hypothesis that $ab = 0$. The simple approach is to test each of the two paths individually and if both are statistically significant, then mediation is indicated [4]. Alternatively, many researchers use a test developed by Sobel [11] that involves standard error of ab . It requires the standard error of a or s_a (which equals a/t_a , where t_a is the t Test of coefficient a) and the standard error of b or s_b (which equals b/t_b). The standard error of ab can be shown to equal approximately the square root of $b^2s_a^2 + a^2s_b^2$. The test of the indirect effect is given by dividing ab by the square root of the above variance and treating the ratio as a Z test (i.e., larger than 1.96 in absolute value is significant at the 0.05 level, two tailed).

The power of the Sobel test is very low and the test is very conservative, yielding too few Type I errors. For instance, in a simulation conducted by Hoyle and Kenny [2], in one condition, the Type I error rate was found sometimes to be below 0.05 even when the indirect effect was not zero. Hoyle and Kenny (1999) recommend having at least 200 cases for this test. Several groups of researchers (e.g., [7, 9]) are seeking an alternative to the Sobel test that is not so conservative.

The mediation model in the Figure 1 may not be properly specified. If the variable X is an intervention, then it can be assumed to be measured without error and that it may cause M and Y , and not vice versa. If the mediator has measurement error (i.e., has less than perfect reliability), then it is likely that effects are biased. The effect of the mediator on the outcome (path b) is underestimated and the effect of the intervention on the outcome (path c') tends to be overestimated (given that ab is positive). The overestimation of this path is exacerbated to the extent to which the mediator is caused by the intervention. To remove the biasing effect of measurement error, multiple indicators of the mediators can be found and a latent variable approach can be employed. One would need to use a structural equation modeling program (e.g., AMOS or LISREL – *see Structural Equation Modeling: Software*) to estimate such a model. If a **latent variable** approach is not used, the

researcher needs to demonstrate that the reliability of the mediator is very high.

Another specification error is that the mediator may be caused by the outcome variable (Y causes M). Because the intervention is typically a manipulated variable, the direction of causation from it is known. However, because both the mediator and the outcome variables are not manipulated variables, they may both cause each other. For instance, it might be the case that the ‘outcome’ may actually mediate the effect of the intervention on the ‘mediator’. Generally, reverse casual effects are ruled out theoretically. That is, a causal effect from Y to M does not make theoretical sense. Design considerations may also lessen the plausibility of reverse causation effects. The mediator should be measured prior to the outcome variable and efforts should be made to determine that the two do not share method effects (e.g., both self-reports from the same person). If one can assume that c' is zero, then reverse causal effects can be estimated. That is, if one assumes that there is complete mediation (X does not cause Y), one can allow for the mediator to cause the outcome and the outcome to cause the mediator.

Smith [10] discussed a method to allow for estimation of reverse causal effects. In essence, both the mediator and the outcome variable are treated as outcome variables and they each may mediate the effects of the other. To be able to employ the Smith approach, there must be for both the mediator and the outcome variable a variable that is known to cause each of them but does not cause the other.

Another specification error is that M does not cause Y , but rather some unmeasured variable causes both variables. For instance, the covariation between M and Y is due to social desirability. Other names for spuriousness are confounding, omitted variables, selection, and the third-variable problem.

The only real solution for spuriousness (besides randomization) is to measure potentially confounding variables. Thus, if there are concerns about social desirability, that variable should be measured and controlled for in the analysis. One can also estimate how strong spuriousness must be to explain the effect [8].

If M is a successful mediator, it is then necessarily correlated with the intervention (path a) and so there will be collinearity. This will affect the precision of the estimates of the last set of regression equations. Thus, the **power** of the test of the coefficients b and c' will be compromised. (The effective sample size for these

tests is approximately $N(1 - a^2)$ where N is the overall sample size and a is a standardized path.) Therefore, if M is a strong mediator (path a), to achieve equivalent power, the sample size might have to be larger than what it would be if M were a weak mediator.

Sometimes the mediator is chosen too close to the intervention and path a is relatively large and b small. Such a *proximal* mediator can sometimes be viewed as a manipulation check. Alternatively, sometimes the mediator is chosen too close to the outcome (a *distal* mediator), and so b is large and a is small. Ideally, the standardized values of a and b should be nearly equal. Even better in terms of maximizing power, standardized b should be somewhat larger than standardized a . The net effect is then that sometimes the power of the test of ab can be increased by lowering the size of a , thereby lowering the size of ab . Bigger is not necessarily better.

The model in the Figure 1 may be more complicated in that there may be additional variables. There might be covariates and there might be multiple interventions (X s), mediators (M s), or outcomes (Y s).

A *covariate* is a variable that a researcher wishes to control for in the analysis. Such variables might be background variables (e.g., age and gender). They would be included in all of the regression analyses. If such variables are allowed to interact with X or M , they would become moderator variables.

Consider the case in which there is X_1 and X_2 . For instance, these variables might be two different components of a treatment. It could then be determined if M mediates the $X_1 - Y$ and $X_2 - Y$ relationships. So in Step 1, Y is regressed on X_1 and X_2 . In Step 2, M is regressed on X_1 and X_2 . Finally, in Steps 2 and 3, Y is regressed on M , X_1 , and X_2 . Structural equation modeling might be used to conduct simultaneous tests.

Consider the case in which M_1 and M_2 mediate the $X - Y$ relationship. For Step 2, two regressions are performed, one for M_1 and M_2 . For Steps 3 and 4, one can test each mediator separately or both in combination. There is greater parsimony in a combined analysis but power may suffer if the two mediators are correlated. Of course, if they are strongly correlated, the researcher might consider combining them into a single variable or having the two serve as indicators of the same latent variable.

Consider the case in which there are two outcome variables, Y_1 and Y_2 . The Baron and Kenny steps would be done for each mediator. Step 2 would need

to be done only once since Y is not involved in that regression.

Sometimes the interactive effect of two independent variables on an outcome variable is mediated by the effect of a process variable. For instance, an intervention may be more effective for men versus women. All the steps would be repeated but now X would not be a main effect but an interaction. The variable X would be included in the analysis, but its effect would not be the central focus. Rather, the focus would be on the interaction of X .

Sometimes a variable acts as a mediator for some groups (e.g., males) and not others (e.g., females). There are two different ways in which the mediation may be moderated. The mediator interacts with some variable to cause the outcome (path b varies) or the intervention interacts with a variable to cause the mediator (path a varies).

In this case, all the variables cause one another. For simple models, one is better off using multiple regression, as Structural Equation Modeling (SEM) tests are only approximate. However, if one wants to test relatively complex hypotheses:

M_1 , M_2 , and M_3 do not mediate the $X - Y$ relationship,

M mediates the X to Y_1 and X to Y_2 relationship,

M mediates the X_1 to Y and X_2 to Y relationship, or a equals b ,

then SEM can be a useful method. Some structural equation modeling computer programs provide measures and tests of indirect effects.

In some cases, the variables X , M , or Y are measured with error, and multiple indicators are used to measure them. SEM can be used to perform the Baron and Kenny steps. However, the following difficulty arises: the measurement model would be somewhat different each time that the model is estimated. Thus, c and c' are not directly comparable because the meaning of Y varies. If, however, the measurement model were the same in both models (e.g., the loadings were fixed to one in both analyses), the analyses would be comparable.

Sometimes, X , M , and Y are measured repeatedly for each person. Judd, Kenny, and McClelland [3] discuss the case in which there are two measurements per participant. They discuss creating difference scores for X , M , and Y , and then examine the extent to which the differences in X and M predict

differences in Y . If the effect of the difference in X affects a difference in Y less when the difference in M is introduced, there is evidence of mediation.

Alternatively, mediational models can be tested using multilevel modeling [5]. Within this approach, the effect of X and M on Y can be estimated, assuming there is a sufficient number of observations for each person. The advantages of multilevel modeling over the previously described difference-score approach are several:

the estimate of the effect is more precise
a statistical evaluation of whether mediation differs by persons
missing data and unequal observations are less problematic

Within multilevel modeling, it does happen that c exactly equals $c' + ab$. The decomposition only approximately holds. Krull and MacKinnon [6] discuss the degree of difference in these two estimates.

One potential advantage of a multilevel mediational analysis is that it can be tested if the mediation effects vary by participant. So M might be a stronger mediator for some persons than for others. If the mediator were coping style and the causal effect were the effect of stress on mood, it might be that a particular coping style is more effective for some people than for others (moderated mediation).

In conclusion, mediational analysis appears to be a simple task. A series of multiple regression analyses are performed, and, given the pattern of statistically significant regression coefficients, mediation can be inferred. In actuality, mediational analysis is not formulaic and careful attention needs to be given to questions concerning the correct specification of the causal model, a thorough understanding of the area of study, and knowledge of the measures and design of the study.

Mendelian Genetics Rediscovered

Introductory Remarks

The schoolchild's notion of the 'rediscovery of Mendel' is that

1. Mendel was the first person to make systematic studies of heredity.
2. He used large enough numbers and mathematical skill to get firm results from which his famous laws could be derived.
3. Because Mendel worked in a monastery in Moravia and published in an obscure journal, Darwin (whose own understanding of genetics was incorrect, thereby leaving a logical flaw in his theory of evolution) never got to discover this work.
4. By coincidence, three scientists, De Vries in Holland, Correns in Germany, and Tschermak in Austria, all independently arrived at the same laws of heredity in 1900, and only then realized Mendel had achieved this 34 years earlier.
5. Rediscovery of these laws paved the way for a complete acceptance of Darwin's theory, with natural selection as the primary mechanism of evolutionary change.

All of these need correction.

Mendel was the First Person to Make Systematic Studies of Heredity

The first of such experiments should probably be associated with the name of Joseph Gottlieb Koelreuter, a German botanist who made seminal contributions to plant hybridization [22] a century before Mendel. Cyrill Napp, a previous abbot of the monastery, of which Mendel himself eventually became abbot, through contact with sheep-breeders, realized the economic importance to the locality of understanding heredity, and sent Mendel to the University of Vienna to be trained in experimental science¹ [21].

In Vienna, Mendel received a very good scientific education in biology and especially in Physics: he had courses from Doppler and von Ettinghausen, and

the latter, in particular, gave him the methodological sophistication to deliberately employ a hypothetico-deductive approach. His Botany professor was Franz Unger, who was a forerunner of Darwin, and who published an evolutionary theory in an *Attempt of a History of the Plant World* in 1852. Mendel reported it was Unger's ponderings on how new species arose from old that prompted him to start his experiments. As the title of his famous paper [13, 14] suggests, rather than seeking some general laws of heredity, Mendel was actually trying to study hybridization, in the tradition, started by Linnaeus, that this might lead to the formation of new species. This was not a mechanism for substantive, macroevolutionary change, and some [5] have doubted whether Mendel actually believed in evolution as an explanation for the entirety of living organisms. He had a copy, annotated by him, of the sixth edition of the *Origin of Species* [2], (which is preserved in the museum in Brno), but certainly Darwin's idea of natural selection being the main mechanism of evolutionary change did not drive Mendel to search for appropriate units of heredity on which this process could work.

Using the garden pea (*Pisum sativum*), Mendel sought contrasting pairs of definitive characteristics, producing a list of seven, namely:

1. ripe seeds smooth or wrinkled
2. cotyledon yellow or green
3. seed coat white or grey
4. ripe pod smooth and not constricted anywhere, or wrinkled and constricted between the seeds;
5. unripe pod green or vivid yellow
6. lots of flowers along the main stem, or only at the end
7. stem tall (6–7 ft) or short (9–18 in.).

When members of these contrasting pairs were crossed, he found a 3:1 ratio in their offspring for that pair of characters. When they were then self-pollinated, the less frequent variant, and one third of the more frequent variant, bred true (gave only offspring the same as themselves), whereas the remaining two thirds of the more frequent variant produced a similar 3:1 ratio. This led him to postulate (or confirmed his postulation), that some hypothetical entity responsible for influencing development in either one way or the other must exist as two copies in a particular plant, but as only one copy in a pollen grain or ovum. If the two copies were of

2 Mendelian Genetics Rediscovered

opposite kind, one kind would always be dominant, and the other recessive, so that the former character would always be expressed in a hybrid², while the other would lie dormant, yet be passed on to offspring. These were only conceptual ‘atoms’, probably not considered by Mendel to be material entities that might one day be chemically isolated. All of this was prior to the discovery of chromosomes, the individual character and continuity of which was suspected, especially by Boveri, in the 1890s, but only finally shown by Montgomery and Sutton in 1901 and 1902.

The three so-called laws of Mendel were neither proposed by him, nor were they really laws. Independent segregation relates to the really important idea that a character which can exist (as we would now say *phenotypically* in two forms can be due to two factors, one inherited from one parent, and one from the other. That such factors (corresponding only with the wisdom of hindsight to today’s genes) may exist, and that there may be two or more alternative forms of them (today’s set of *alleles*) were the really important ideas of Mendel that his experiments revolutionarily enshrine. Independent assortment of one pair of factors in relation to some other such pair is not a law, since it depends upon the location of the different pairs on different chromosomes. Mendel was either extremely lucky to select seven pairs of characteristics presumably related to the seven different chromosomes of this species, a chance of 1/163, or he neglected noise in his data (in fact due to what we now know as *linkage*) or perhaps attributed it to a procedural error, and rejecting such data, and arrived at the ‘correct’ result by calculation based on prior assumptions. And the third ‘law’, of dominance and recessiveness, of course (as Mendel himself knew) only applies to certain pairs of alleles, such as those in which the recessive allele results in the inability to synthesize a particular enzyme, which may be manufactured in sufficient quantity in the presence of just one copy of the dominant allele [8]. In many cases the heterozygote may be intermediate between, or qualitatively different from either homozygote.

He used Large Enough Numbers and Mathematical Skill to Get Firm Results from which his famous Laws could be Derived

Certainly, the numbers of plants and crosses Mendel used were appropriately large for the probabilistic

nature of the task in hand. Mendel knew nothing of statistical proofs, but realized that large samples would be needed, and on the whole tested large numbers in order to produce reliable results. Mendel’s carefully cast three laws led with impeccable logic to the prediction of a 9:3:3:1 ratio for the independent segregation of two pairs of ‘factors’ (*Elemente*)³. Now, the actual ratios which Mendel seems to have claimed to have found, fit these predictions so well that they have been deemed (by **R. A. Fisher**, no less [7]) to be too good, that is very unlikely to have been obtained by chance, given the numbers of crosses Mendel carried out. Charitably, Jacob Bronowski [1] created the memorable image of Mendel’s brother friar ‘research assistants’ innocently counting out the relative numbers of types of peas so as to please Gregor, rather than Mendel himself inventing them. Another explanation might be that Mendel went on collecting data until the predicted ratios emerged, and then stopped, poor practice leading in effect to an unwitting rigging of results. Fisher made his criticism, which is by no means universally accepted [12, 19], in the context of a paper [7] that also patiently attempts to reconstruct what actual experiments Mendel may have done, and overall eulogizes unstintingly the scientific prestige of Mendel. The ethics do not matter⁴: the principles by means of which he set out to predict the expected outcomes are what Mendel is famous for, since we now know, for pairs of nonlethal alleles with loci on separate chromosomes, that these rules correctly describe the default situation. It is a long way from here, however, to the ‘modern synthesis’ [6, 9], and neither Mendel, nor initially ‘Mendelism’ (in the hands of the three ‘Rediscoverers’), were headed in that direction.

Because Mendel worked in a monastery in Moravia and published in an obscure journal, Darwin (whose own understanding of genetics was incorrect, thereby leaving a logical flaw in his theory of evolution) never got to discover this work

Gregor Mendel gave an oral paper, and later published his work in the proceedings of the local society of naturalists in Brünn, Austria (now Brno, Czech Republic), in 1866. The *Verhandlungen* of the Brünn Society were sent to the Royal Society and the Linnaean Society (*inter alia*), but there seems to be no

evidence for the notion that Darwin had a personal copy (uncut, and therefore unread).

Even if Darwin had come across Mendel's paper, the fact that it was in German and proposed ideas different from his own theory of *pangenesis* would have been sufficient, some have suggested, to discourage Darwin from further browsing. A more interesting (alternative history) question (put by Mayr [12], and answered by him in the negative) is whether Darwin would have appreciated the significance of Mendel's work, had he carefully read it.

Darwin was inclined towards a 'hard' view of inheritance (that it proceeded to determine the features of offspring with no relation to prevailing environmental conditions). He nevertheless made some allowance, increasingly through his life, for 'soft' inheritance, for example, in the effects of use and disuse on characters, such as the reduction or loss of eyes in cave-dwelling species. (This we would now attribute to the cessation of stabilizing selection, plus some possible benefit from jettisoning redundant machinery.) Such 'Lamarckian' effects were allowed for in Darwin's own genetic theory, his 'provisional hypothesis of pangenesis' [3], in which hereditary particles, which Darwin called *gemmules*, dispersed around the individual's body, where they would be subject to environmental influences, before returning to the reproductive organs to influence offspring. The clear distinction, made importantly by the great German biologist Weismann [23], between germ plasm and somatic cells, with the hereditary particles being passed down an unbroken line in the germ plasm, uninfluenced by what happened in the soma, thus banishing soft inheritance⁵, came too late for Darwin and Mendel. After it, the discoveries of Mendel became much easier to 'remake'.

Darwin always ranked natural selection as a more potent force in evolutionary change, however, and this was a gradual process working on the general variation in the population. Darwin was aware of 'sports' and 'freaks', and thus in a sense had the notion of mutations (which De Vries – see subsequent passage – made the basis of his theory of evolution), but these were not important for Darwin's theory, and he might have seen the explicit discontinuities of Mendel's examples as exceptions to general population variation. The work of Fisher and others in population genetics, which explains the latter in terms of the former, thereby reconciling Mendelism

with natural selection, had yet to be done: this provided the key to the so-called 'Modern Synthesis' [9] of the 1940s.

We have seen that Darwin, with the gemmules of his pangenesis theory, had himself postulated a particulate theory of heredity. However, he, together with Galton, Weismann, and De Vries, in their particulate theories of inheritance, postulated the existence of multiple identical elements for a given character in each cell nucleus, including the germ cells. This would not have led to easily predictable ratios. For Mendel, only one *Elemente* would enter a gamete. In the heterozygote, the unlike elements (*differierenden Elemente*) would remain separate, though Mendel for some reason assumed that blending would occur (in the homozygote) if the two elements were the same (*gleichartigen Elemente*). So perhaps Darwin would not have seen Mendel's work as the answer to Jenkin's devastating criticism [10] of his theory, based on the notion of blending inheritance, that after a generation or two, the effects of natural selection would be diluted to nothing. This, of course, is the statistical principle of **regression to the mean** in a Gaussian distribution, which Galton, Darwin's cousin, later emphasized. Galton could not see how the average of a population could shift through selection, and looked to genetic factors peculiar to those at the tail ends of distributions to provide a source of change, as in positive eugenic plans to encourage those possessed of 'hereditary genius' to carefully marry those with similar benefits.

Of the 40 reprints of [14], Mendel is known to have sent copies to two famous botanists, A. Kerner von Marilaun at Innsbruck, and Nägeli, a Swiss, but by that time professor of botany in Munich, and famous for his own purely speculative theory of inheritance in conformity with current physics (a kind of String theory of its day!). Now Nägeli was a dampening influence upon Mendel (we only have Mendel's letters to Nägeli, not vice versa). Nägeli did not cite Mendel in his influential book [17], nor did he encourage Mendel to publish his voluminous breeding experiments with *Pisum* and his assiduous confirmations in other species. Had Mendel ignored this advice the meme of his work would probably not have lain dormant for a generation, nor would it have needed to be 'rediscovered'. Nägeli simply urged Mendel to test his theory on hawkweeds (*Hieracium*), which he did, with negative results: we now know parthenogenesis is common in this genus. With his

4 Mendelian Genetics Rediscovered

training in physics (a discipline famous for vaulting general laws, perhaps bereft of the only Golden Rule of Biology – like that of the Revolutionist in George Bernard Shaw’s *Handbook* – which is that there is no Golden Rule), Mendel asserted that ‘A final decision can be reached only when the results of detailed experiments from the most diverse plant families are available.’ The *Hieracium* work he did publish in 1870: it was to be his only other paper, before he ascended his institution’s hierarchy and was lost to administration the following year.

By Coincidence Three Scientists, De Vries in Holland, Correns in Germany, and Tschermak in Austria, all Independently Arrived in 1900 at the Same Laws of Heredity and only then Realized Mendel had done this 34 Years Earlier

At the turn of the twentieth century, Correns and Tschermak were both working on the garden pea also, and found references to Mendel’s paper during their literature searches. Most important was its citation in Focke’s review of plant hybridization, *Die Pflanzen-Mischlinge* (1881), (though Focke did not understand Mendel’s work), and is the only one of the 15 actual citations that is relevant to its content that does little to stimulate the reader to consult the original paper⁶. De Vries also found the reference. It would be like harking back to a 1970 paper now, but in a strikingly smaller corpus of publications.

Hugo (Marie) de Vries was a Dutchman, in his early fifties in 1900, and Professor of Botany at the University of Amsterdam. In 1886, he became interested in the many differences between wild and cultivated varieties of the Evening Primrose (*Oenothera lamarckiana*), and the sudden appearance, apparently at random, of new forms or varieties when he cultivated this plant, for which he coined the term ‘mutations’. Their sudden appearance seemed to him to contradict the slow, small variations of Darwin’s natural selection, and he thought that it was through mutations that new species were formed, so that their study provided an experimental way of understanding the mechanism of evolution.

De Vries had already proposed a particulate theory of inheritance in his *Intracellular Pangenesis* (1889) [4], and in 1892 began a program of breeding experiments on unit characters in several plant

species. With large samples, he obtained clear segregations in more than 30 different species and varieties, and felt justified in publishing a general law. In a footnote to one of three papers given at meetings and quickly published in 1900, he stated that he had only learned of the existence of Mendel’s paper⁷ after he had completed most of these experiments and deduced from his own results the statements made in this text. Though De Vries carefully attributed originality to Mendel in all his subsequent publications, scholars [5] have argued about the veracity of this assertion. Some of his data, based on hundreds of crosses, we would now see as quite good approximations to 3 : 1 ratios in F2 crosses, but in his writings around this time, De Vries talked of 2 : 1 or 4 : 1 ratios, or quoted percentage splits such as 77.5% : 22.5% or 75.5% : 24.5%. Mayr [12] opines that it cannot be determined whether or not De Vries had given up his original theory of multiple particles determining characteristics in favor of Mendel’s single elements. Perhaps through palpable disappointment at having been anticipated by Mendel, he did not follow through to the full implications of Mendel’s results as indicative of a general genetic principle, seeing it as only one of several mechanisms, even asserting to Bateson that ‘Mendelism is an exception to the general rule of crossing.’

De Vries became more concerned about his mutation theory of evolution (*Die Mutationstheorie*, 1901); he was the first to develop the concept of mutability of hereditary units. However, rather than the point gene mutations later studied by Morgan, De Vries’ mutations were mostly chromosome rearrangements resulting from the highly atypical features that happen to occur in *Oenothera*, the single genus in which De Vries described them.

Carl Erich Correns, in his mid-thirties in 1900, was a German botany instructor at the University of Tübingen, was also working with garden peas, and similarly claimed to have achieved a sudden insight into Mendelian segregation in October 1899. Being busy with other work, he only read Mendel a few weeks later, and he only rapidly wrote up his own results after he had seen a reprint of one of the papers of De Vries in 1900. He readily acknowledged Mendel’s priority, and thought his own rediscovery had been much easier, given that he, unlike Mendel, was following the work of Weismann. Correns went on to produce a lot more supportive evidence throughout his career in a number of German

universities, and he postulated a physical coupling of genetic factors to account for the consistent inheritance of certain characters together, anticipating the development of the concept of linkage by the American geneticist Thomas Hunt Morgan.

Though his 1900 paper⁸ showed no understanding of the basic principles of Mendelian inheritance [15, 16], the third man usually mentioned as a rediscoverer of Mendel is the Austrian botanist Erich Tschermak von Seysenegg, not quite 30 in 1900. Two years before, he had begun breeding experiments, also on the garden pea, in the Botanical Garden of Ghent, and the following year he continued these in a private garden, whilst doing voluntary work at the Imperial Family's Foundation at Esslingen near Vienna. Again, it was while writing up his results that he found a reference to Mendel's work that he was able to access in the University of Vienna. It duplicated, and in some ways went beyond his own work. In his later work, he took up a position in the Academy of Agriculture in Vienna in 1901 and was made a professor five years later. He applied Mendel's principles to the development of new plants such as a new strain of barley, an improved oat hybrid, and hybrids between wheat and rye.

It is really William Bateson (1861–1926) who should be included as the most influential of those who were the first to react appropriately to the small opus by Mendel lurking in the literature, even though his awareness of it was due initially to De Vries. Bateson was the first proponent of Mendelism in English-speaking countries, and coined the term 'genetics' (1906). Immediately after the appearance of papers by De Vries, Correns and Tschermak, Bateson reported on these to the Royal Horticultural Society in May 1900, and then read, and was inspired by, Mendel's paper *Experiments in Plant Hybridisation* shortly thereafter. Bateson was also responsible for the first English translation of this paper, which was published in the *Journal of the Royal Horticultural Society* in 1901.

Bateson's is a fascinating case of a brilliant and enthusiastic scientist, who turned against his earlier Darwinian insights, and adopted, with considerable grasp, the new principles of Mendelism. Paradoxically, this served to obstruct the eventual realization that these were in fact the way to vindicate and finally establish the overarching

explanatory power of Darwin's evolution by natural selection.

Initially, Bateson shared the interests of his friend Weldon, who had been influenced by Pearson's statistical approach to study continuous variation in populations, but when he himself came to do this in the field, choosing fishes in remote Russian lakes, he strengthened his conviction that natural selection could not produce evolutionary change from the continuum of small variations he discovered. He urgently sought some particulate theory of heredity to account for the larger changes he thought necessary to drive evolution, and thought he had found this in Mendelism. He was stimulated by De Vries's notion that species formation occurred when mutations spread in a population, and when he later read a 1900 paper by De Vries describing the 3:1 ratio results (in the train on his way to a meeting of the Royal Horticultural Society), he changed the text of his paper to claim that Galton's regression law was in need of amendment. Bateson became an insightful and influential exponent of the new Mendelism, carrying out confirmatory experiments in animals, and coining terms (in addition to 'genetics') which soon became key conceptual tools, including 'allelomorph' (later shortened to 'allele'), 'homozygote' and 'heterozygote'.

The term 'gene', however, was coined by the Danish botanist William Johannsen. Unfortunately, he sought to define each gene in terms of the specific phenotypic character for which it was deemed responsible. The distinction between 'genotype' and 'phenotype' was drawn early by **G. Udny Yule** in Cambridge. Yule, unlike Johannsen, insightfully saw that if many genes combined to influence a particular character, and if this character were a relatively simple unit, which a phenotypic feature arbitrarily seized upon an experimenter might well not be, then Mendelism might deliver the many tiny changes beloved of Darwin. This was an idea whose time was yet to come.

Rediscovery of these Laws Paved the way for a Complete Acceptance of Darwin's Theory with Natural Selection as the Primary Mechanism of Evolutionary Change

In the end it did, but not until after a long period of misunderstanding and dispute, which was finally brought to an end by means of the Modern Synthesis.

As we have seen, there were two main sides to the dispute. On the one hand were the so-called biometricians, led by **Karl Pearson**, who defended Darwinian natural selection as the major cause of evolution through the cumulative effects of small, continuous, individual variations (which they assumed passed from one generation to the next without being limited by Mendel's laws of inheritance). On the other were the champions of 'Mendelism', who were mostly also mutationists: they felt that if we understood how heredity worked to produce big changes, then *ipso facto* we would have an explanation for the surges of the evolutionary process.

The resolution of the dispute was brought about in the 1920s and 1930s by the mathematical work of the population geneticists, particularly J. B. S. Haldane and R. A. Fisher in Britain, and Sewall Wright in the United States. They showed that continuous variation was entirely explicable in terms of Mendel's laws, and that natural selection could act on these small variations to produce major evolutionary changes. Mutationism became discredited. Recent squabbles about the relative size and continuity of evolutionary changes, between those tilted towards relative, rapid, quite large changes 'punctuating' long periods of unchanging equilibrium, and those in favor of smaller and more continuous change, are but a pale reflection of the earlier dispute.

In its original German, Mendel's paper repetitively used the term *Entwicklung*, the nearest English equivalent to which is probably 'development' [20]. It was also combined, German-fashion, with other words, as in *Entwicklungsreihe*, (developmental series); *die Entwicklungsgeschichte* (the history of development); *das Entwicklungs-Gesetz* (the law of development). Mendel at least (if not all of the 'rediscoverers' and their colleagues who thought they were addressing the same problems as Mendel), would have been delighted by the present day rise of developmental genetics, that is, the study of how the genetic material actually shapes the growth and differentiation of the organism, made possible, among other advances, by the discovery of the genetic code and the mapping of more and more genomes. He might have been surprised too, by the explanatory power of theories derived from population genetics, based on his own original work, combined with natural selection, to account for the evolution of behavior, and of human nature.

Notes

1. According to the presentation by Roger Wood (Manchester University, UK), in a joint paper with Vitezslav Orel (Mendelianum, Brno, Czech Republic) at a conference in 2000, at the Academy of Sciences in Paris, to mark the centenary of the conference of the Academy to which De Vries reported.
2. Mendel was not clear about the status of species versus varieties (not an easy issue today) and used the term hybrid for crosses at either level, whereas we would confine it to species crosses today.
3. With the first two pairs of characters listed above Mendel actually seems to have obtained 315 round yellow: 108 round green: 101 wrinkled yellow: 32 wrinkled green.
4. As the noted historian of psychology Leslie Hearnshaw once suggested to me, the fact that Mendel went on to publish his subsequent failures to obtain similar results in the Hawkweed (*Hieracium*) does much to allay any suspicions as to his honesty.
5. Weismann was right in principle, but instead of the cytological distinction, we have today the 'central dogma' of biochemical genetics, that information can pass from DNA to proteins, and from DNA to DNA, but not from protein to DNA [11].
6. 'Mendel's numerous crossings gave results which were quite similar to those of Knight, but Mendel believed that he found constant numerical relationships between the types of the crosses.' (Focke 1881, quoted by Fisher [7].)
7. In his book entitled *Origins of Mendelism* [18], the historian Robert Olby relates that just prior to publication 'from his friend Professor Beijerinck in Delft [De Vries] received a reprint of Mendel's paper with the comment: "I know that you are studying hybrids, so perhaps the enclosed reprint of the year 1865 by a certain Mendel is still of some interest to you"'.

Mendelian Inheritance and Segregation Analysis

Gregor Mendel (1822–1884), Abbot at the St Thomas Monastery of the Augustinian Order in Brunn, conducted the seminal experiments that demonstrated the existence of genes and characterized how they are transmitted from parents to offspring, thus laying the foundation of the science of genetics. Mendel chose the garden pea as his experiment organism, and selected seven characteristics that are dichotomous and therefore easy to measure. Mendel's experiments, and their results, can be summarized as follows:

1. After repeated inbreeding, plants became uniform in each characteristic (e.g., all tall). These are known as pure lines.
2. When two pure lines with opposite characteristics are crossed (e.g., tall and short), one of the characteristics is present in all the offspring (e.g., they are all tall). The offspring are said to be the F1 generation, and the characteristic present in F1 (e.g., tall) is said to be dominant, while the alternative, absent characteristic (e.g., short) is said to be recessive.
3. When two plants of the F1 generation are crossed, the offspring (F2) display the dominant (e.g., tall) and recessive (e.g., short) characteristics in the ratio 3:1. This cross is called an *intercross*.
4. When an F1 plant is crossed with the parental recessive pure line, the offspring display the dominant and recessive characteristics in the ratio 1:1. This cross is called a *backcross*.

Mendel explained these observations by formulating the law of segregation. This law states that each individual contains two inherited factors (or genes) for each pair of characteristics, and that during reproduction one of these two factors is transmitted to the offspring, each with 50% probability. There are two alternative forms of the genes, called *alleles*, corresponding to each dichotomous character. When the two genes in an individual are of the same allele, then the individual's genotype is said to be homozygous, otherwise it is said to be heterozygous. An individual with heterozygous genotyping (e.g., Aa) has the same characteristic as an individual with homozygous

genotype (e.g., AA) of the dominant allele (e.g., A). The explanations of the above observations are then as follows:

1. Repeated inbreeding produces homozygous lines (e.g., AA, aa) that will always display the same characteristic in successive generations.
2. When two pure lines (AA and aa) are crossed, the offspring (F1) will all be heterozygous (Aa), and therefore have the same characteristic as the homozygous of the dominant allele (A).
3. When two F1 (Aa) individuals are crossed, the gametes A and a from one parent combine at random with the gametes A and a from the other to form the offspring genotypes AA, Aa, aA, and aa, in equal numbers. The ratio of offspring with dominant and recessive characteristics is therefore 3:1.
4. When an F1 (Aa) individual is crossed with the recessive (aa) pure line, the offspring will be 50:50 mixture of Aa and aa genotypes, so that the ratio of offspring with dominant and recessive characteristics is therefore 1:1.

The characteristic 3:1 and 1:1 ratios among the offspring of intercross and backcross, respectively, are known as Mendelian segregation ratios. Mendel's work was the first demonstration of the existence of discrete heritable factors, although the significance of this was overlooked for many years, until 1900 when three botanists, separately and independently, rediscovered the same principles.

Classical Segregation Analysis

The characteristic 1:1 and 3:1 segregation ratios provide a method of checking whether a disease in humans is caused by mutations at a single gene. For rare dominant disease, the disease mutation (A) is likely to be rare, so that individuals homozygous for the disease mutations (AA) are likely to be exceedingly rare. A mating between affected and unaffected individuals is therefore very likely to be a backcross (Aa × aa), with a predicted segregation ratio of 1:1 among the offspring. An investigation of such matings to test the segregation ratio of offspring against the hypothetical value of 1:1 is a form of classical segregation analysis.

For rare recessive conditions, the most informative mating is the intercross (Aa × Aa) with a predicted

2 Mendelian Inheritance and Segregation Analysis

segregation ratio of 3:1. However, because the condition is recessive, the parents are both normal and are indistinguishable from other mating types (e.g., $aa \times aa$, $Aa \times aa$). It is therefore necessary to recognize $Aa \times Aa$ matings from the fact that an offspring is affected. This, however, introduces an ascertainment bias to the “apparent segregation ratio”. To take an extreme case, if all families in the community have only one offspring, then ascertaining families with at least one affected offspring will result in all offspring being affected. A number of methods have been developed to take ascertainment procedure into account when conducting segregation analysis of putative recessive disorders. These include the proband method, the singles method, and maximum likelihood methods.

Complex Segregation Analysis

Complex segregation analysis is concerned with the detection of a gene that has a major impact on the phenotype (called a *major locus*), even though it is not the only influence and that other genetic and environmental factors are involved in determining the phenotype. The involvement of other factors reduces the strength of relationship between the major locus and the phenotype. Because of this, it is not possible to deduce the underlying mating type from the phenotypes of family members. Instead, it is necessary to consider all the possible mating types for each family. Even if a specific mating type could be isolated, the segregation ratio would not be expected to follow classical Mendelian ratios. For

these reasons, this form of segregation analysis is said to be complex.

Complex segregation analysis is usually conducted using **maximum likelihood methods** under one of two models. The first is a generalized single locus model with generalized transmission parameters. This differs from a Mendelian model in two ways. First, the probabilities of disease given **genotype** (called *penetrances*) are not necessarily 0 or 1, but can take intermediate values. Secondly, the probabilities of transmitting an allele (e.g., A) given parental genotype (e.g., AA, Aa, and aa) are not necessarily 1, 1/2, or 0, but can take other values. A test for a major locus is provided by a test of whether these transmission probabilities conform to the Mendelian values (1, 1/2, and 0). The second model is the mixed model, which contains a single major locus against a polygenic background. A test for a major locus is provided by a test of this mixed model against a pure polygenic model without a major locus component. Both forms of analyses can be applied to both qualitative (e.g., disease) and quantitative traits, and are usually conducted in a maximum likelihood framework, with adjustment for the ascertainment procedure. The generalized transmission test and the mixed model test have been combined into a unified model and implemented in the POINTER program. Other methods for complex segregation analysis, for example, using regressive models, have also been developed.

Meta-Analysis

Introduction

Small Progress in Behavioral Science?

It is well known that the results of empirical studies are subject to random fluctuation if they are based on samples of subjects instead of on the complete population on which the study is focused. In a study evaluating the effect of a specific treatment, for instance, the population **effect size** is typically estimated using the effect size that is observed in the sample. Traditionally, researchers deal with the uncertainty associated with the estimates by performing significance tests or by constructing **confidence intervals** around the effect size estimates. In both procedures, one refers implicitly to the sampling distribution of the effect sizes, which is the distribution of the observed effect sizes if the study had been replicated an infinite number of times.

Unfortunately, research in behavioral science is characterized by relatively small-sample studies, small population effects and large initial differences between subjects [49, 58]. Consequently, confidence intervals around effect sizes are often unsatisfactorily large and thus relatively uninformative, and the **power** of the significance tests is small. Researchers, at least those who are aware of the considerable uncertainty about the study results, therefore often conclude their research report by a call for more research.

During the last decennia, several topics were indeed investigated several times, some of them even dozens of times. Mosteller and Colditz [44] talk about an information explosion. Yet, reviewers of the results of studies evaluating a similar treatment often are disappointed. While in some studies positive effects are found, in other studies, no effects or even negative effects are obtained. This is not only true for sets of studies that differ from each other in the characteristics of the subjects that were investigated or in the way the independent variable is manipulated, but also for sets of studies that are more or less replications of each other. Reviewers have a hard job to see the wood for the trees and often fall back on personal strategies to summarize the results of a set of studies. Different reviewers therefore often come to different conclusions, even if they discuss the

same set of studies [49, 58]. The conflicting results from empirical studies have brought some to the pessimistic idea that researchers in these domains do not progress, and have driven some politicians and practitioners toward relying on their own feelings instead of on scientific results. The rise of the meta-analysis offered new perspectives.

The Meta-analytic Revolution

Since the beginning of the twentieth century, there have been some modest attempts to summarize study results in a quantitative and objective way (e.g., [48] and [29]; see [59]). It was, however, not before the appearance of an article from Glass in 1976 [23] that the idea of a quantitative integration of study results was explicitly described. Glass coined the term ‘meta-analysis’ and defined it as

‘... the analysis of analyses. I use it to refer to the statistical analysis of a large collection of analysis results from individual studies for the purpose of integrating the findings’. (p. 3)

The introduction of the term meta-analysis and the description of simple meta-analytic procedures were the start of a spectacular rise of the popularity of quantitative research synthesis. Fiske [17] even used the term meta-analytic revolution. Besides the popularity of meta-analysis in education [41], applications showed up in a wide variety of research domains [46]. The quantitative approach gradually supplemented or even pushed out the traditional narrative reviews of research literature [35]. Another indication of the growing popularity of meta-analysis was the mounting number and size of meta-analytic handbooks [1].

The growing attention for meta-analysis gradually affected the views on research progress in behavioral science. Researchers became aware that even if studies are set up in a very similar way, conflicting results due to random fluctuation alone are not surprising, especially when study results are described on the significant–nonsignificant dichotomy. By quantitatively combining the results of several similar trials, meta-analyses have the potential of averaging out the influence of random fluctuation, resulting in more steady estimates of the overall effect and a higher power in testing this overall effect size. Meta-analytic methods were developed in order to distinguish the random variation in study results from ‘true’ between

study heterogeneity, and in order to explain the latter by estimating and testing moderating effects of study characteristics.

Performing a Meta-analysis

A meta-analysis consists of several steps (see e.g., [9] for an extensive discussion):

1. *Formulating the research questions or hypotheses and defining selection criteria.* Just like in primary research, a clear formulation of the research question is crucial for meta-analytic research. Together with practical considerations, the research question results in a set of criteria that are used to select studies. The most common selection criteria relate to the population from which study participants are sampled, the dependent and the independent variables and their indicators, and the quality of the study. Note that formulating a very specific research question and using very strict selection criteria eventually results in a set of similar studies for which the results of the meta-analysis are relatively easy to interpret, but at the other side of the coin, the set of studies will also be relatively small, at the expense of the reliability of the results.

2. *Looking for studies investigating these questions.* A thorough search includes an exploration of journals, books, doctoral dissertations, published or unpublished research reports, conference papers, and so on. Sources of information are, for instance, databases that are printed or available online or on CD-ROM, contacts with experts in the research domain, and reference lists of relevant material. To avoid bias in the meta-analytic results (see below), it is a good idea to use different sources of information and to include published as well as unpublished study results. Studies are selected on the basis of selection criteria from the first step.

3. *Extracting relevant data.* Study outcomes and characteristics are selected, coded for each study, and assembled in a database. The study characteristics can be used later in order to account for possible heterogeneity in study outcomes.

4. *Converting study results to a comparable measure.* Study results are generally reported by means of descriptive statistics (means, standard deviations, etc.), test statistics (t , F , χ^2 , ...) or P values, but the way of reporting is usually very different from

study to study. Moreover, variables are typically not measured on the same scale in all studies. The comparison of the study outcomes, therefore, requires a conversion to a common standardized measure. One possibility is to use P values. The meaning of P values does not depend on the way the variables are measured, or on the statistical test that is used in the study. A disadvantage of P values, however, is that it depends not only on the effect that is observed but also on the sample size. A very small difference between two groups, for instance, can be statistically significant if the groups are large, while a large difference can be statistically nonsignificant if the groups are relatively small. Although techniques for combining P values have been described, in current meta-analyses, usually measures are combined that express the magnitude of the observed relation, independently of the sample size and the measurement scale. Examples of such standardized effect size measures are the **Pearson's correlation coefficient** and the **odds ratio**. A popular effect size measure in behavioral science is the standardized mean difference, used to express the difference between the means of an experimental and a control condition on a continuous variable, or more generally the difference between the means of two groups:

$$\delta = \frac{\mu_E - \mu_C}{\sigma}, \quad (1)$$

with μ_E and μ_C equal to the population mean under the experimental and the control condition, respectively, and σ equal to the common population standard deviation. The population effect size δ is estimated by its sample counterpart:

$$d = \frac{\bar{x}_E - \bar{x}_C}{s_p}, \quad (2)$$

with $\bar{x}_E$ and $\bar{x}_C$ equal to the sample means, and s_p equal to the pooled sample standard deviation. Assuming normal population distributions with a common variance under both conditions, the sampling distribution of d is approximately normal with mean δ and variance equal to [30]:

$$\hat{\sigma}_d^2 = \frac{n_E + n_C}{n_E n_C} + \frac{d^2}{2(n_E + n_C)} \quad (3)$$

5. *Combining and/or comparing these results and possibly looking for moderator variables.* This step

forms the essence of the meta-analysis. The effect sizes from the studies are analyzed statistically. The unknown parameters of one or more meta-analytic models are estimated and tested. Common statistical models and techniques to combine or compare effect sizes will be illustrated extensively below by means of an example.

6. Interpreting and reporting the results. In this phase, the researcher returns to the research question(s) and tries to answer these questions based on the results of the analysis. The research report ideally describes explicitly the research questions, the inclusion criteria, the sources used in the search for studies, a list of the studies that were selected, the observed effect sizes, the study sample sizes, and the most important study characteristics. It should also contain a description of how study results were converted to a common measure, which models, techniques, estimation procedures, and software were used to combine these measures, and which assumptions were made for the analyses. It is often a good idea to illustrate the meta-analytic results graphically, for instance, using a funnel plot, a **stem-and-leaf plot**, a **histogram** or a plot of the interval estimates of the observed study effect sizes and the overall effect size estimate (see below).

An Example

Raudenbush [50, 51] combined the results of 18 experiments investigating the effect of teacher expectations on the intellectual development of their pupils. In each of the studies, the researcher tried to create high expectancies for an experimental group of pupils, while this was not the case for a control group. The observed differences between groups were converted to the standardized mean difference (Table 1). Table 1 also describes for each study the length of contact between teacher and pupil prior to the expectancy induction, as well as the standard error of the observed effect sizes (3).

Since the sampling distribution of the standardized mean difference is approximately normal with a standard deviation estimated by the standard error of estimation, one could easily construct confidence intervals around the observed effect sizes. The confidence intervals are presented in Figure 1.

Note that somewhat more than half of the observed effect sizes are larger than zero. In three studies, zero is not included in the confidence interval, and the (positive) observed effect sizes therefore are statistically significantly different from zero. Following Cohen [6], calling a standardized mean difference of

Figure 1 Confidence intervals for the observed effect sizes and for the estimated mean effect size under a fixed effects model (FEM) or a random effects model (REM)

0.20, 0.50, and 0.80 a small, moderate, and large effect respectively, almost all observed effect sizes suggest that there is generally only a small effect. With the naked eye, it is difficult to see whether there is a general effect of teacher expectancy, and how large this effect is. Moreover, it is difficult to see whether the observed differences between study outcomes are due to sampling variation, or whether the observed differences between study outcomes are due to the intrinsic differences between studies. In the following section, we show how these questions can be dealt with in meta-analysis. Different models are illustrated, which differ in complexity and in the underlying assumptions.

Fixed Effects Model

As discussed above, observed effect sizes can be conceived of as randomly fluctuating. If in a specific study another sample would have been taken (from the same population), the observed effect size would probably not have been exactly the same. Suppose that differences in the meta-analytic data set between the observed effect sizes can be entirely accounted for by sampling variation. In this case, we can model the study results as:

$$d_j = \delta + e_j, \quad (4)$$

with d_j the observed effect size in study j , δ the common population effect size, and e_j a residual due to sampling variation. The primary purpose of the meta-analysis is then to estimate or test the overall effect, δ . The overall effect is usually estimated by averaging the observed effects. Since, in general, the population effect size is estimated more reliably in

large studies, effect sizes are sometimes weighted by the study sample sizes in calculating the average. A similar approach, resulting in a decreased *MSE*, is to weight by the precision of the estimates, this is the inverse of the squared standard error. The precision is estimated as the inverse of the sampling variance estimate (as given in Equation 3).

$$\hat{\delta} = \frac{\sum_{j=1}^k w_j d_j}{\sum_{j=1}^k w_j},$$

$$\text{with } w_j = \frac{1}{\hat{\sigma}_{d_j}^2} \text{ and } k \text{ the total number of studies} \quad (5)$$

The precision of the estimate of the overall effect is the sum of the individual precisions. The standard error of the estimate of the overall effect is estimated by:

$$SE(\hat{\delta}) = (\text{precision})^{-1/2} = \left(\sum_{j=1}^k \frac{1}{\hat{\sigma}_{d_j}^2} \right)^{-1/2} \quad (6)$$

For the example, the estimate of the overall effect is 0.060, with a corresponding standard error of 0.036. Since the sampling distribution of the overall effect size estimate is again approximately normal, an approximate 95% confidence interval equals $[0.060 - 1.96 * 0.036; 0.060 + 1.96 * 0.036] = [-0.011; 0.131]$. Because zero is included in the confidence interval, we conclude that the overall effect size estimate is statistically not significant at the 0.05-level. This is equivalent to comparing the estimate divided by the standard error with a standard normal distribution, $z = 1.67$, $p = 0.09$. The confidence interval around the overall effect size estimate is also presented in Figure 1. It can be seen that the interval is much smaller than the confidence intervals of the individual studies, illustrating the increased precision or power when estimating or testing a common effect size by means of a meta-analysis.

The assumption that the population effect size is the same in all studies is frequently unlikely. Studies often differ in, for example, the operationalization of the dependent or the independent variable and the

population from which the study participants are sampled, and it is often unlikely that these study or population characteristics are unrelated to the effect that is investigated. Before using the fixed effects techniques, it is therefore recommended to test the homogeneity of the study results. A popular homogeneity test is the test of Cochran [5]. The test statistic

$$Q = \sum_{j=1}^k \frac{(d_j - \hat{\delta})^2}{\hat{\sigma}_{d_j}^2} \quad (7)$$

follows approximately a chi-square distribution with $(k - 1)$ degrees of freedom¹. For the example, the homogeneity test reveals that it is highly unlikely that such relatively large differences in observed effect sizes are entirely due to sampling variation, $\chi^2(18) = 35.83$, $p = 0.007$. The assumption of a common population effect size is relaxed in the following models.

For the sake of completeness, we want to remark that the fixed effects techniques (*see Fixed and Random Effects; Fixed Effect Models*) described above are actually not only appropriate when the population effect size is the same for all studies, but also when the population effect size differs from study to study but the researcher is interested only in the population effect sizes that are studied. In the last case, (5) is not used to estimate a common population effect size, but rather to estimate the mean of the population effect sizes studied in the studies included in the meta-analytic data set.

Random Effects Model

Cronbach [10] argued that the treatments that are investigated in a meta-analytic set of empirical studies often can be regarded as a random sample from a population of possible treatments. As a result, studies often do not investigate a common population effect size, but rather a distribution of population effect sizes, from which the population effect sizes from the studies in the data set represent only a random sample. While in the fixed effects model described above (4) the population effect size is assumed to be constant over studies, in the random effects model, the population effect size is assumed to be a stochastic variable (*see Fixed and Random Effects*). The population effect size that is estimated in a specific study is modeled as the mean of the population distribution of effect sizes plus a random residual [11,

31, 35]:

$$\delta_j = \gamma + u_j \quad (8)$$

An observed effect size deviates from this study-specific population effect size due to sampling variation:

$$d_j = \delta_j + e_j \quad (9)$$

Combining (8 and 9) results in:

$$d_j = \gamma + u_j + e_j \quad (10)$$

If d_j is an unbiased estimate of δ_j , the variance of the observed effect size is the sum of the variance of the population effect size and the variance of the observed effect sizes around these population effect sizes:

$$\sigma_{d_j}^2 = \sigma_{\delta}^2 + \sigma_{(d_j|\delta_j)}^2 = \sigma_u^2 + \sigma_e^2 \quad (11)$$

Although better estimators are available [70], an obvious estimate of the population variance of the effect sizes therefore is [31]:

$$\hat{\sigma}_{\delta}^2 = s_d^2 - \frac{\sum_{j=1}^k \hat{\sigma}_{d_j|\delta_j}^2}{k} \quad (12)$$

To estimate γ , the mean of the population distribution of effect sizes, one could again use the precision weighted average of the observed effect sizes (5). While in the fixed effects model the precision associated with an observed effect size equals the inverse of the sampling variance alone, the precision based on a random effects model equals the inverse of the sampling variance plus the population variance. Since this population variance is the same for all studies, assuming a random effects model instead of a fixed effects model has an equalizing effect on the weights.

For the example, the estimate of the variance in population effect sizes is 0.080, the estimate of the mean effect size 0.114. Assuming that the distribution of the true effect sizes is normal, 95% of the estimated population distribution of effect sizes therefore is located between -0.013 and 0.271. For the example, the equalizing effect of using a random effects model resulted in an estimate of the mean effect size that is larger than that for the fixed effects model (0.060), since in the example larger standard errors are in general associated with larger observed effect sizes.

The standard error of the estimate can again be estimated using (6), but in this case, (11) is used to

estimate the variance of the observed effect sizes. The standard error therefore will be larger than for the fixed effects model, which is not surprising: the mean effect size can be estimated more precisely if one assumes that in all studies exactly the same effect size is estimated. For the example, the standard error of the estimate of the mean effect size equals 0.079, resulting in a 95% confidence interval equal to $[-0.041; 0.269]$. Once more, the interval includes zero, which means that even if there is no real effect, it is not unlikely that a mean effect size estimate of 0.114 or a more extreme one is found, $z = 1.44$, $p = 0.15$.

Since the effect is assumed to depend on the study, the researcher may be interested in the effect in one or a few specific studies. Note that the observed effect sizes are in fact estimates of the study-specific population effect sizes. Alternatively, one could use the mean effect size estimate to estimate the effect in each single study. While the first kind of estimate seems reasonable if studies are large (and the observed effect sizes are more precise estimates of the population effect sizes), the second estimate is sensible if studies are much alike (this is if the between study variance is smaller). The *empirical Bayes* estimate of the effect in a certain study is an optimal combination of both kinds of estimates. In this combination, more weight will be given to the mean effect if studies are more similar and if the study is small. Hence, in these situations, the estimates are more ‘shrunk’ to the mean effect. Because of this property of shrinkage, empirical Bayes estimates are often called *shrinkage estimates*. Empirical Bayes estimates ‘borrow strength’ from the data from other studies: the *MSE* associated with the empirical Bayes estimates of the study effect sizes is, in general, smaller than the *MSE* of the observed effect sizes. For more details about empirical Bayes estimates, see, for example, [51] and [52].

In the random effects model, population effect sizes are assumed to be exchangeable. This means that it is assumed that there is no prior reason to believe that the true effect in a specific study is larger (or smaller) than in another study. This assumption is quite often too restrictive, since frequently study characteristics are known that can be assumed to have a systematic moderating effect. In Table 1, for instance, the number of weeks of prior contact between pupils and teachers is given for each study. The number of weeks of prior contact could be

supposed to affect the effect of manipulating the expectancy of teachers toward their pupils, since manipulating the expectancies is easier if teachers do not know the pupil yet. In the following models, the moderating effect of study characteristics is modeled explicitly.

Fixed Effects Regression Model

Several methods have been proposed to account for moderator variables. Hedges and Olkin [31], for example, proposed to use an adapted **analysis of variance** to explore the moderating effect of a categorical study characteristic. For a continuous study characteristic, they proposed to use a fixed effects regression model. In this model, study outcomes differ due to sampling variation and due to the effect of study characteristics:

$$d_j = \delta_j + e_j = \gamma_0 + \sum_{s=1}^S \gamma_s W_{sj} + e_j, \quad (13)$$

with W_{sj} equal to the value of study j on the study characteristic s , and S the total number of study characteristics included in the model. Note that the effect of a categorical study characteristic can also be modeled by means of such a fixed effects regression model, by means of dummy variables indicating the category the study belongs to. The fixed effects regression model simplifies to the fixed effects model described above in case the population effect sizes do not depend on the study characteristics.

Unknown parameters can be estimated using the weighted least squares procedure, weighting the observed effect sizes by their (estimated) precision as we did before for the fixed effects model (5). Details are given by Hedges and Olkin [31]. If, for the example, one study characteristic is included with levels 0, 1, 2, and 3 for respectively 0, 1, 2, and 3 or more weeks of prior contact, the estimate of the regression intercept equals 0.407, with a standard error of 0.087, while the estimated moderating effect of the number of weeks equals -0.157 with a standard error of 0.036. This means that if there was no prior contact between pupils and teachers, elevating the expectancy of teachers can be expected to have a positive effect, $z = 4.678$, $p < 0.001$, but this treatment effect decreases significantly with the length of prior contact, $z = -4.361$, $p < 0.001$.

Mixed Effects Model

In the fixed effects regression model, possible differences in population effect sizes are entirely attributed to (known) study characteristics. The dependence of δ_j on the study characteristics is considered to be nonstochastic. The *random effects regression model* accounts for the possibility that population effect sizes vary partly randomly, partly according to known study characteristics:

$$d_j = \delta_j + e_j = \gamma_0 + \sum_{s=1}^s \gamma_s W_{sj} + u_j + e_j, \quad (14)$$

Since in the random effects regression model the population effect sizes depend on fixed effects (the γ 's) and random effects (the u 's), the model is also called a *mixed effects model*. Raudenbush and Bryk [51] showed that the mixed effects meta-analytic model is a special case of a hierarchical linear model or **linear multilevel model**, and proposed to use **maximum likelihood estimation** procedures that are commonly used to estimate the parameters of multilevel models, assuming normal residuals. For the example, the maximum likelihood estimate of the residual between study variance equals zero. This means that for the example the model simplifies to the fixed effects regression model, and the parameter estimates and corresponding standard errors for the fixed effects are the same as the ones given above. Differences between the underlying population effect sizes are explained entirely by the length of prior contact between pupils and teachers.

Threats for Meta-analysis

Despite its growing popularity, meta-analysis has always been a point of controversy and has been the subject of lively debates (see, e.g., [13], [14], [33], [34], [62], [67] and [72]). Critics point to interpretation problems due to, among other things, combining studies of dissimilar quality, including dependent study results, incomparability of different kinds of effect size measures, or a lack of essential data to calculate effect size measures. Another problem is the 'mixing of apples and oranges' due to combining studies investigating dissimilar research questions or using dissimilar study designs, dissimilar independent, or dependent variables or participants from dissimilar populations.

The criticism on meta-analysis that probably received most attention is the *file drawer problem* [57], which refers to the idea that the drawers of researchers may be filled with statistically nonsignificant unpublished study results, since researchers are more inclined to submit manuscripts describing significant results, and manuscripts with significant results are more likely to be accepted for publication. In addition, the results of small studies are less likely to be published, unless the observed effect sizes are relatively large. One way to detect the file drawer problem and the resulting *publication bias* is to construct a *funnel plot* [40]. A funnel plot is a scatter plot with the study sample size as the vertical axis and the observed effect sizes as the horizontal axis. If there is no publication bias, observed effect sizes of studies with smaller sample sizes will generally be more variable, while the expected mean effect size will be independent of the sample size. The shape of the scatter plot therefore will look like a symmetric funnel. In case of publication bias, most extreme negative effect sizes, or statistically nonsignificant effect sizes are not published and thus less likely to be included in the meta-analytic data set, resulting in a gap in the funnel plot for small studies and small or negative effect sizes. A funnel plot of the data from the example² is presented in Figure 2.

It can be seen that there is indeed some evidence for publication bias: for small studies there are some extreme positive observed effect sizes but no extreme negative observed effect sizes, resulting in a higher mean effect size for smaller studies. The asymmetry of the funnel plot, however, is largely due to only two effect sizes, and may well be caused by coincidence. This is confirmed by performing a distribution free statistical test for testing the correlation between effect size and sample size, based

Figure 2 Funnel plot for the example data

on **Spearman's rho** [2]. While there is a tendency of a negative correlation, this relation is statistically not significant at the 0.05-level, $z = -1.78$, $p = .08$. Since a negative correlation between effect size and the sample size is expected in the presence of publication bias, an alternative approach to assess publication bias is to include the sample size as a moderator variable in a meta-analytic regression model. More information about methods for identifying and correcting for publication bias can be found in [2].

One might expect that some of the problems will become less important due to the fact that since the rise of meta-analysis, researchers and editors became aware of the importance of publishing nonsignificant results and of reporting exact P values, effect sizes, or test statistics, and meta-analysts became aware of the importance of looking for nonpublished study results. In addition, some of the criticisms are especially applicable to the relatively simple early meta-analytic techniques. The problem of 'mixing apples and oranges', for instance, is less pronounced if the heterogeneity in effect sizes is appropriately modeled using a random effects and/or by using moderator variables. 'Mixing apples and oranges' can even yield interesting information if a regression model is used, and the 'kind of fruit' is included in the model by means of one or more moderator variables. The use of the framework of multilevel models for meta-analysis further can offer an elegant solution for the problem of multiple effect size measures in some or all studies: a three-level model can be used, modeling within-study variation in addition to sampling variation and between study variation (see [20] for an example). Nevertheless, a meta-analysis remains a tenuous statistical analysis that should be performed rigorously.

Literature and Software

The article by Glass [23] and the formulation of some of the simple meta-analytic techniques by Glass and colleagues, (see e.g., [24], [25] and [64]), might be considered as the breakthrough of meta-analysis. Besides the calculation of the mean and standard deviation of the effect sizes, moderator variables are looked for by calculating correlation coefficients between study characteristics and effect sizes, by means of a multiple regression analysis

or by performing separate meta-analyses for different groups of studies. In the 1980s, these meta-analytic techniques were further developed, and the focus moved from estimating the mean effect size to detecting and explaining study heterogeneity. Hunter, Schmidt, and Jackson [35, 39] especially paid attention to possible sources of error (e.g., sampling error, measurement error, range restriction, computational, transcriptional, and typographical errors) by which effect sizes are affected, and to the correction of effect sizes for these artifacts. Rosenthal [58] described some simple techniques to compare and combine P values or measures of effect size. A more statistically oriented introduction in meta-analysis, including an overview and discussion of methods for combining P values, is given by Hedges and Olkin [31].

Rubin [61] proposed the random effects model for meta-analysis, which was further developed by DerSimonian and Laird [11] and Hedges and Olkin [31]. Raudenbush and Bryk [51] showed that the general framework of hierarchical linear modeling encompasses a lot of previously described meta-analytic methodology, yielding similar results [70], but at the same time extending its possibilities by allowing modeling random and fixed effects simultaneously in a mixed effects model. Goldstein, Yang, Omar, Turner, and Thompson [27] illustrated the flexibility of the use of hierarchical linear models for meta-analysis. The flexibility of the hierarchical linear models makes them also applicable for, for instance, combining the results from single-case empirical studies [68, 69]. Parameters of these hierarchical linear models are usually estimated using maximum likelihood procedures, although other estimation procedures could be used, for instance Bayesian estimation [22, 65].

An excellent book for basic and advanced meta-analysis, dealing with each of the steps of a meta-analysis is Cooper and Hedges [8]. This and other instructional, methodological, or application-oriented books on meta-analysis are reviewed by Becker [1]. More information about one of the steps in a meta-analysis, converting summary statistics, test statistics, P values and measures of effect size to a common measure is found in [8], [43], [53], [54], [60] and [66].

Several packages for performing meta-analysis are available, such as META [63] that implements techniques for fixed and random effects models and can

be downloaded free of charge together with a manual from http://www.fu-berlin.de/gesund/gesu_engl/meta_e.htm, Advanced Basic meta-analysis [45], implementing the ideas of Rosenthal, and MetaWin for performing meta-analyses using fixed, random, and mixed effects models and implementing parametric or resampling based tests (<http://www.metawinsoft.com>). Meta-analyses however can also be performed using general statistical packages, such as SAS [73]. A more complete overview of specialized and general software for performing meta-analysis, together with references to software reviews is given on the homepages from William Shadish (<http://faculty.ucmerced.edu/wshadish/Meta-Analysis%20Links.htm>) and Alex Sutton (<http://www.prw.le.ac.uk/epidemio/personal/ajs22/meta>). Since meta-analytic models can be considered as special forms of the hierarchical linear model, software, and estimation procedures for hierarchical linear models can be used. Examples are MLwiN (<http://multilevel.ioe.ac.uk>), based on the work of the *Centre for Multi-level Modelling* from the *Institute of Education* in London [26], HLM (<http://www.ssicentral.com/hlm/hlm.htm>), based on the work of Raudenbush and Bryk [52] and SAS proc MIXED [74].

Notes

1. The sampling distribution of Q often is only roughly approximated by a chi-square distribution, resulting in a conservative or liberal homogeneity test. Van den Noortgate & Onghena [71], therefore, propose a bootstrap version of the homogeneity test.
2. Equation 3 was used to calculate group sizes based on the observed effect sizes and standard errors given in Table 1. In each study, the two group sizes were assumed to be equal.

Microarrays

The culture of molecular biology values categorical results, and a generation of scientists used to bands on gels and DNA sequence is confronting statistics for the first time as they design microarray experiments and analyze data. This can sometimes be seen in the style of data presentation used, for example, the red-green false color images often used to summarize differences between the signal from a pair of RNA samples hybridized to the same array in an experiment using two fluorescent labels. This kind of experimental design allows many of the possible sources of measurement error to be at least equalized between a pair of samples, but gives no information on the reliability of the result. This has led to a widespread understanding of microarrays as a survey method, whose indicative results must be checked by other methods. As new uses for microarrays are conceived and costs come down, this is changing and more attention is being paid to statistical methods. This is particularly true for the highly standardized, industrially produced arrays such as the Affymetrix GeneChips.

The Affymetrix Array

I will discuss the Affymetrix product in this article, though many aspects of the discussion are applicable to other kinds of microarrays. I will also limit the discussion to arrays used for gene expression analysis, although once again much of the discussion will also be relevant to microarrays designed for genotyping and other purposes. I will start with a brief description of the method, going through the steps of data analysis from the raw image upwards, addressing experimental design last.

The principle of measurement in microarrays is nucleic acid hybridization. Immobilized on the array, are known sequences of DNA (normally, although RNA or synthetic NA analogues would also be possible) known as *probes*. Reacted with these in solution is a mixture of unknown (labeled RNA or DNA) fragments to be analyzed, known as *targets* (traditionally these terms were used the other way around). The targets bind to the probes in (ideally) a sequence-specific manner and fill the available probe sites to an extent that depends on

the target concentration. After the unbound target is washed away, the quantity of target bound to each probe is determined by a fluorescence method.

In the case of Affymetrix arrays, the probes are synthesized *in situ* using a proprietary photolithography method, which generates an unknown but small quantity of the desired sequence on an ever-smaller feature size. On current products the feature size is $11 - \mu\text{m}$ square, allowing nearly 300 000 features on a 6-mm square chip. With arrays made by mechanical spotting or similar methods, locating features and generating a representative intensity value can be demanding, but grid location and adjustment are relatively straightforward using the physical anchorage and fluorescent guidespots in the Affymetrix system. Each of the grid squares (representing a feature) contains approximately 25 pixels after an outer rim has been discarded; these are averaged. With current protocols, saturated ($\text{SD}=0$) cells are rare.

Normalization and Outliers

Because the amplified fluorescence assay used in the Affymetrix system is in a single color, experimental fluctuations in labeling, hybridization, and scanning need to be taken into account by normalizing across arrays of an experiment. This has been an extensively studied topic in array studies of all kinds and there are many methods in use [10]. A related issue is the identification of outlying intensity values likely to be due to production flaws, imperfect hybridization, or dust specks. The Affymetrix software performs a simple scaling using a chip-specific constant chosen to make the trimmed mean of intensities across the entire chip a predetermined value. This is probably adequate for modest differences in overall intensity between experiments done in a single series, but it does assume linearity in the response of signal to target concentration, which is unlikely to be true across the entire intensity range. Several excellent third party programs that are free, at least for academic use, offer other options. *dChip* [9], for example, finds a subset of probes whose intensity ranking does not vary across an experimental set of chips and uses this to fit a normalization curve. An excellent toolbox for exploring these issues is provided by packages from the Bioconductor project, particularly *affy* [5].

Summarizing the Probeset

The high density made possible by the photolithographic method allows multiple probes to be used for each transcript (also called *probeset*), which means that the (still not fully understood) variation in the binding characteristics of different oligonucleotide sequences can be buffered or accounted for. For each 25-nucleotide probe (perfect match (PM)), a control probe with a single base in the central (13th) position is synthesized. This was conceived as a control for the sequence specificity of the hybridization or a background value, but this is problematic. Each probeset consists (in current Affymetrix products) of 11 such perfect match-mismatch probe pairs. The next level of data reduction is the distillation of the probeset into a single intensity value for the transcript. Methods of doing this remain under active discussion. Early Affymetrix software used a proprietary method to generate signal values from intensities, but Microarray Suite (MAS) versions 5 and later use a relatively well-documented robust mean approach [7]. This is a robust mean (Tukey's biweight) for the perfect match PM probes and separately for the mismatch (MM) probes. The latter is subtracted and the result is set to zero where $MM > PM$. Other summary methods use model-fitting with or without MM values or thermodynamic data on nucleic acid annealing, to take into account the different performance of different probe sequences. These may have effects on the variability of measurements [8, 13, 12]. It may, under some circumstances, make sense to treat the measurements from individual probes as separate measurements [1].

Statistical Analysis of Replicated Arrays

Once a list of signal values (in some arbitrary units) is available, the interesting part begins and the user is largely on his own. By this I mean that specialized microarray software does not offer very extensive support for statistical evaluation of the data. An honorable exception is dChip which offers **analysis of variance** (ANOVA) through a link with R, and the *affy* package from Bioconductor [5] which is implemented in the same R statistical computing environment. It may be a wise design decision to limit the statistical features of specialized microarray software in that there is nothing unique about the data,

which really should be thought about and analyzed like other experimental data. The signal value for a given probeset is like any other single measurement, and variance and replication need to be considered just as in other types of experiments. Of course the issue of **multiple testing** requires particular attention, since tens of thousands of transcripts are measured in parallel.

Having worked with the experimental data and reduced it to a value for each probeset (loosely, transcript), the analyst can transfer the data to the statistical package he likes best. Because statistical tests are done on each of thousands of transcripts, a highly programmable and flexible environment is needed. R is increasingly popular for this purpose and there are several microarray related packages available. The *affy* package (part of BioConductor) can be installed from a menu in recent versions of R, and offers methods and data structures to do this quite conveniently. Most of the available methods for summarizing probesets are available and are practical on a personal computer (PC) with one gigabyte (GB) of random access memory (RAM). Whether processing of the data is done in R or with other software, it is a real time saver, especially for the beginner, to have the data in a structure that is not unnecessarily complicated – normally a dataframe with one row for each probeset (and the probeset ID as row name), and columns for each chip with brief names identifying the sample.

In advance of testing hypotheses, it may be good to *filter* the data, removing from consideration datasets that have no usable information, which may also aid in thinking about how much multiple testing is really being done. It is also the time to consider whether the data should be transformed. Because outlying signals should have been dealt with in the process of normalization and probeset summarization, the chief criterion for filtration is expression level. Traditional molecular biology wisdom is that roughly half of all genes are expressed in a given tissue. Whether a qualitative call of expression/no expression actually corresponds to a biological reality is open to question, and there is the added complication that any tissue will consist of multiple cell types with differing expression patterns. In practice, differences between weak expression signals will be dominated by noise. MAS 5 provides a presence/absence call for each probeset which can be used as a filtering criterion. One complication is that the fraction

of probesets ‘present’ varies from one hybridization to the next, and is used as an experimental quality measure. An alternative would be to consider those probesets whose signal values exceed the mean (or some other quantile) across the whole array.

It is common to log-transform signal data; this is convenient in terms of informal fold-change criteria, although the statistical rationale is usually unclear. The distribution of signal values across a single array is clearly not normally distributed, but the distribution that is generally of interest is for a given probeset across multiple arrays, where there are fewer data.

The natural starting point in analyzing the data from a set of microarrays is to look for differences between experimental groups. This will generally be a more or less straightforward ANOVA, applied to each of the probesets on the array used. Depending on the design of the experiment, it may be useful to use a **generalized linear mixed model** to reflect the different sources of variance. Some additional power should also be available from the fact that the dispersion of measurements in the thousands of probesets across the set of microarrays is likely to be similar. A reasonable approach to this may be ‘variance shrinking’ [4]. The most difficult and controversial aspect of the analysis is the extent to which the assumptions of ANOVA, in particular, independence within experimental groups, are violated. Peculiarly extreme views on this (especially with regard to inbred strains), as well as bogus inflated significance, are encountered. Pragmatically there will be some violation, but as long as the design and analysis take careful and fair account of the most important sources of variance, we are unlikely to be fooled.

The resulting vector of P values, or more to the point, of probesets ranked by P values, then needs to be evaluated in light of the experimental question and your own opinions on multiple testing. As a starting point, Bonferroni correction (see **Multiple Comparison Procedures**) for the number of probesets is extremely, perhaps absurdly, conservative, but in many experiments there will be probesets that will differ even by this criterion. Many probesets will have background levels of signal for all samples, and among those that present something to measure, there will be many that are highly correlated. False-discovery-rate (FDR) methods [2, 11] offer a sensible

alternative, but in general, experimental results will be a ranked list of candidates, and where this list is cut off may depend on practicalities, or on other information. On the Affymetrix arrays, there is a substantial amount of duplication (multiple probesets for the same transcript), which may give additional support to some weak differences. In other cases, multiple genes of the same pathway, gene family, or genomic region might show coordinate changes for which the evidence may be weak when considered individually. This argues for considerable exploration of the data, and also public archiving of complete data sets.

Hierarchical clustering of expression patterns across chips using a distance measure such as $1 - |r|$, where r is the Pearson correlation between the patterns of two transcripts, is an often used example of a way of exploring the data for groups of transcripts with coordinate expression patterns. This is best done with a filtered candidate list as described earlier, because the bulk of transcripts will not differ, and little will be learned by clustering noise at high computational cost. There is a growing amount of annotation on each transcript and a particularly convenient set of tools for filtering, clustering, and graphic presentation with links to annotation is provided by dChip.

In some experiments, the objective is not so much the identification of interesting genes as classification of samples (targets), such as diagnostic samples [6]. Here, classification techniques such as **discriminant analysis** or supervised **neural networks** can be used to allocate samples to prespecified groups.

Experimental Design

In developing an experimental design, initially scientists tend to be mesmerized by the high cost of a single determination, which is currently about £500/\$1000 in consumables for one RNA on one array. The cost of spotted cDNA arrays (especially the marginal cost for a laboratory making their own) can be much lower, but because of lower spotting densities and lower information per spot (because of greater technical variation), it is not simple to make a fair comparison. The Affymetrix software is designed to support the side-by-side comparison so loved by molecular biologists. A ‘presence’ call is produced complete with a P value for each probeset, and there is provision for pairwise analysis in

which a 'difference' call with a P value is produced. These treat the separate probes of each probeset as separate determinations in order to provide a semblance of statistical support to the values given. This is not a fair assessment of even the purely technical error of the experimental determination, because it knows nothing of the differences in RNA preparation, amplification, and labeling between the two samples. Overall intensity differences between chips resulting from differences in labeling efficiency should be largely dealt with by normalization, but it is easy to see how there could be transcript-specific differences. RNA species differ in stability (susceptibility to degradation by nucleases) and length, for example. Nonetheless, the protocols are quite well standardized and the two chip side-by-side design does give a reasonably robust indication of large differences between samples, which is also what has traditionally been sought from the two color spotted cDNA array experiment. The need for replicates starts to become obvious when the resulting list of candidate differences is reviewed – it may be fairly long, and the cost of follow up of the levels of many individuals by other measurement methods such as quantitative polymerase chain reaction (PCR) mounts quickly.

The greatest source of variation that needs to be considered in the experimental design is the biological variation in the experimental material. This is particularly so when dealing with human samples where it has to be remembered that every person (except for identical twins) is a unique genetic background that has experienced a unique and largely uncontrolled environment. Further variation comes from tissue collection, and it is often uncertain whether tissue samples are precisely anatomically comparable. This biological variation can be physically averaged using pooling. The temptation to do this should be resisted as much as is practical because it does not give any information on variance. Realistically, experimental designs are decided after dividing the funds available by the cost of a chip. There is no rule of thumb for how many replicates are necessary, since this depends on the true effect size and the number of groups to be compared. Even with eight experimental groups and four replicates of each, there is only 80% power to detect between-group variability of one within-group SD. Whether this corresponds to a 10% difference or a twofold difference depends on the variability of

the biological material (*see Sample Size and Power Calculation*).

Rather than minimizing cost by minimizing array replicates, value for money can ideally be maximized by using materials which can be mined many times. An outstanding example of this is the WebQTL database [3], where microarray data on a growing number of tissues are stored along with other phenotype data for the BxD mouse recombinant inbred panel. Here, the value of the data for repeated mining is particularly great, because the data derives from a genetically reproducible biological material (inbred mouse strains).

Mid- P Values

One of the most important statistical procedures is the hypothesis test, in which a formal analysis is conducted to produce a P value, which is used to summarize the strength of evidence against the null hypothesis. There are a few complicated testing procedures that are not based on a test statistic [3]. However, these procedures are the exception, and the general rule is that a test statistic is the basis for a hypothesis test. For example, if one were to test the fairness of a coin, one could toss the coin a given number of times, say ten times, and record the number of heads observed. This number of heads would serve as the test statistic, and it would be compared to a known null reference distribution, constructed under the assumption that the coin is, in fact, fair. The logic is an application of *modus tollens* [1], which states that if A implies B, then not B implies not A. If the coin is fair, then we expect (it is likely that we will see) a certain number of heads. If instead we observe a radically different number of heads, then we conclude that the coin was not fair.

How many heads do we need to observe to conclude that the coin is not fair? The distance between the observed data and what would be predicted by the null hypothesis (in this case, that the coin is fair) is generally measured not by the absolute magnitude of the deviation (say the number of heads minus the null expected value, five), but rather by a P value. This P value is the probability, computed under the assumption that the null hypothesis is true, of observing a result as extreme as, or more extreme than, the one we actually observed. For example, if we are conducting a one-sided test, we would like to conclude that the coin is not fair if, in fact, it is biased toward producing too many heads. We then observe eight heads out of the ten tosses. The P value is the probability of observing eight, nine, or ten heads when flipping a fair coin. Using the binomial distribution (see **Binomial Distribution: Estimating and Testing Parameters**), we can compute the P value, which is $[45 + 10 + 1]/1024$, or 0.0547. It is customary to test at the 0.05 significance level, meaning that the P value would need to be less than 0.05 to be considered significant.

Clearly, eight of ten heads is not significant at the 0.05 significance level, and we cannot rule out that the coin is fair. One may ask if we could have rejected

the null hypothesis had we observed instead nine heads. In this case, the P value would be $11/1024$, or 0.0107. This result would be significant at the 0.05 level and gives us a decision rule: reject the null hypothesis if nine or ten heads are observed in ten flips of the coin. Generally, for continuous distributions, the significance level that is used to determine the decision rule, 0.05 in this case, is also the null probability of rejection, or the probability of a Type I error. But in this case, we see that a Type I error occurs if the coin is fair and we observe nine or ten heads, and this outcome occurs with probability 0.0107, not 0.05. There is a discrepancy between the intended Type I error rate, 0.05, and the actual Type I error rate, 0.0107.

It is unlikely that there would be any serious objection to having an error probability that is smaller than it was intended to be. However, a consequence of this conservatism is that the power to detect the alternative also suffers, and this would lead to objections. Even if the coin is biased toward heads, it may not be so biased that nine or ten heads will typically be observed. The extent of conservatism will be decreased with a larger sample size, but there is an approach to dealing with conservatism without increasing the sample size. Specifically, consider these two probabilities, $P\{X > k\}$ and $P\{X \geq k\}$, where X is the test statistic expressed as a random variable (in our example, the number of heads to be observed) and k is the observed value of X (eight in our example). If these two quantities, $P\{X > k\}$ and $P\{X \geq k\}$, were the same, as they would be with a continuous reference distribution for X , then there would be no discreteness, no conservatism, no associated loss of power, and no need to consider the mid- P value.

But these two quantities are not the same when dealing with a discrete distribution, and using the latter makes the P value larger than it ought to be, because it includes the null probability of all outcomes with test statistic equal to k . That is, there are 45 outcomes (ordered sets of eight heads and two tails), and all have the same value of the test statistic, eight. What if we used just half of these outcomes? More precisely, what if we used half the probability of these outcomes, instead of all of it? We could compute $P\{X > k\} = 0.0107$ and $P\{X = k\} = 0.04395$, so $P\{X \geq k\} = 0.0107 + 0.04395 = 0.0547$ (as before), or we could use instead $0.0107 + (0.04395)/2 = 0.0327$. This latter

computation leads to the mid- P value. In general, the mid- p is $P\{X > k\} + (1/2)P\{X = k\}$. See [4–7] for more details regarding the development of the mid- P value.

Certainly, the mid- P value is smaller than the usual P value, and so it is less conservative. However, it does not allow one to recover the basic quantities, $P\{X > k\}$ and $P\{X \geq k\}$. Moreover, it is not a true P value, as it is anticonservative, in the sense that it does not preserve the true Type I error rate [2]. One modification of the mid- P value is based on recognizing the mid- P value as being the midpoint of the interval $[P\{X > k\}, P\{X \geq k\}]$. Instead of presenting simply the midpoint of this interval, why not present the entire interval, in the form $[P\{X > k\}, P\{X \geq k\}]$? This is the P value interval [2], and, as mentioned, it has as its midpoint the mid- P value. But it also tells us the usual P value as its upper endpoint, and it shows us the ideal P value, in the absence of any conservatism, as its lower endpoint. For the example, the P value interval would be (0.0107, 0.0547).

Minimum Spanning Tree

Introduction

The minimum spanning tree (MST) problem is one of the oldest problems in graph theory, dating back to the early 1900s [13]. MSTs find applications in such diverse areas as least cost electrical wiring, minimum cost connecting communication and transportation networks, network reliability problems, minimum stress networks, clustering and numerical taxonomy (see **Cluster Analysis: Overview**), algorithms for solving traveling salesman problems, and multiterminal network flows, among others. At the theoretical level, its significance stems from the fact that it can be solved in polynomial time – the execution time is bounded by a polynomial function of the problem size – by greedy type algorithms. Such algorithms always take the best immediate solution while searching for an answer. Because of their myopic nature, they are relatively easy to construct, but in many optimization problems they lead to suboptimal solutions. Problems solvable by greedy algorithms have been identified with the class of matroids. Furthermore, greedy algorithms have been extensively studied for their complexity structure and MST algorithms have been at the center of this endeavor.

In this paper, we present the main computational aspects of the problem and discuss some key applications in statistics, probability, and data analysis.

Some Useful Preliminaries

In this section, we introduce several concepts that prove useful for the developments that follow.

Definition 1: An *undirected graph* $G = (V, E)$ is a structure consisting of two sets V and E .

The elements of V are called *vertices* (nodes) and the elements of E are called *edges*. An edge $e = (u, v)$, $u, v \in V$ is an unordered pair of vertices u and v .

An example of an undirected graph is shown in Figure 1. Notice that there is a self-loop (an edge whose endpoints coincide) for vertex E and a multiedge between nodes B and E.

Definition 2: A *path* $p = \{v_0, v_1, \dots, v_k\}$ in a graph G from vertex v_0 to vertex v_k is a sequence of vertices such that (v_i, v_{i+1}) is an edge in G for $0 \leq i \leq k$. Any edge may be used only once in a path.

Definition 3: A *cycle* in a graph G is a path whose end vertices are the same; that is, $v_0 = v_k$.

Notice the cycle formed by the edges connecting nodes D, F, and G.

Definition 4: A graph G is said to be *connected* if there is a path between every pair of vertices.

Definition 5: A *tree* T is a *connected* graph that has *no cycles* (acyclic graph).

Definition 6: A *spanning tree* T of a graph G is a subgraph of G that is a tree and contains all the vertices of G .

A spanning tree is shown in Figure 2.

2 Minimum Spanning Tree

Figure 3 A simple undirected graph and its adjacency matrix W

Figure 4 A weighted undirected graph and its adjacency matrix W

A useful mathematical representation of an undirected graph $G = (V, E)$ is through its *adjacency* matrix W , which is a $|V| \times |V|$ matrix with $W_{ij} = 1$, if an edge exists between vertices i and j and $W_{ij} = 0$, otherwise. An example of an undirected graph and its adjacency matrix is given in Figure 3. It can easily be seen that W is a binary symmetric matrix with zero diagonal elements.

In many cases, the edges are associated with nonnegative weights that capture the strength of the relationship between the end vertices. This gives rise to a *weighted* undirected graph that can be represented by a symmetric matrix with nonnegative entries, as shown in Figure 4.

The Minimum Spanning Tree Problem

The MST problem is defined as follows:

Let $G = (V, E)$ be a connected weighted graph. Find a spanning tree of G whose total edge-weight is a minimum.

Remark: When V is a subset of a metric space (e.g., V represents points on the plane equipped with some distance measure), then a solution T to the MST problem represents the shortest network connecting all points in V .

As most graph theory problems, the MST one is very simple to state, and has attracted a lot of interest for finding its solution. A history of the problem and the algorithmic approaches proposed for its solution can be found in Graham and Hell [13] with an update in Nesetril [20]. As the latter author observes ‘(the MST) is a cornerstone of combinatorial optimization and in a sense its cradle’.

We present next two classical (textbook) algorithms due to Prim [21] and Kruskal [16], respectively. For each algorithm, the solution T is initialized with the minimum weight edge and its two endpoints. Furthermore, let $v(T)$ denote the number of vertices in T and $v(F)$ the number of vertices in a collection of trees; that is a *forest*.

Prim’s algorithm: While $v(T) < |V|$ do:

- interrogate edges (in increasing order of their weights) until one is found that has one of its endpoints in T and its other endpoint in $V - T$ and has the minimum weight among all edges that satisfy the above requirement.
- Add this edge and its endpoint to T and increase $v(T)$ by 1.

Kruskal’s algorithm: While $v(F) < |V|$ do:

Figure 5 The progression of the two classical MST algorithms with a total cost of 7.4

- interrogate edges (in increasing order of their weights) until one is found that does not generate a cycle in the current forest F .
- Add this edge and its endpoints to F and increase $v(F)$ by 1 or 2.

An illustration of the progression of the two algorithms on a toy graph is shown in Figure 5. Notice that whereas Prim's algorithm grows a single tree, Kruskal's algorithm grows a forest. For a proof of the optimality of these two algorithms, see [23].

These two algorithms take in the worst case scenario approximately $|E| \times \log |V|$ step to compute the solution, which is mainly dominated by the sorting step. Over the last two decades better algorithms with essentially a number of steps proportional to the number of edges have been proposed by several authors; see [5, 7, 11]. However, the work of Moret et al. [19] suggests that in practice Prim's algorithm outperforms on average its competitors.

Applications of the MST

In this section, we provide a brief review of some important applications and results of the MST in statistics, data analysis, and probability.

Multivariate Two-sample Tests

In a series of papers, Friedman and Rafsky [8, 9] proposed the following generalization of classical

nonparametric two-sample tests for multivariate data (see **Multivariate Analysis: Overview**): suppose we have two multivariate samples on $\mathbb{R}^d$, $\mathcal{X}_n = \{X_1, X_2, \dots, X_n\}$ from a distribution F_X and $\mathcal{Y}_m = \{Y_1, Y_2, \dots, Y_m\}$ from another distribution F_Y . The null hypothesis of interest is $H_0: F_X = F_Y$ and the alternative hypothesis is $H_1: F_X \neq F_Y$. The proposed test procedure is as follows:

1. Generate a weighted graph G whose $n + m$ nodes represent the data points of the pooled samples, with the edge weights corresponding to Euclidean distances between the points.
2. Construct the MST, T of G .
3. Remove all the edges in T for which the endpoints come from different samples.
4. Define the test statistic $R_{n,m} = \#$ of disjoint subtrees.

Using the asymptotic normality of $R_{n,m}$ under H_0 , the null hypothesis is rejected at the significance level α , if

$$\frac{R_{n,m} - E(R_{n,m})}{\sqrt{\text{Var}(R_{n,m}|C_{n,m})}} < \Phi^{-1}(\alpha), \quad (1)$$

where $\Phi^{-1}(\alpha)$ is the α -quantile of the standard normal distribution and $C_{n,m}$ the number of edge pairs of T that share a common node. Expressions for $E(R_{n,m})$ and $\text{Var}(R_{n,m}|C_{n,m})$ are given in [8]. In [14] it is further shown that $R_{m,n}$ is asymptotically distribution-free under H_0 , and that the above test is universally consistent.

Figure 6 Demonstration of the multivariate two-sample runs test

A demonstration of the two-sample test is given in Figure 6. The 40 $\square$ points come from a two-dimensional multivariate mean zero normal distribution with $\sigma_1^2 = \sigma_2^2 = .36$ and $\sigma_{12} = 0$. The 30 $\star$ points come from a two-dimensional multivariate normal distribution with mean vector $(2, 2)$ and $\sigma_1^2 = \sigma_2^2 = 1$ and $\sigma_{12} = 0$ (see **Catalogue of Probability Density Functions**). The value of the observed test statistic is $R_{40,30} = 6$ and the z -score is around -6.1 , which suggests that H_0 is rejected in favor of H_1 .

Remark: In [8], a Smirnov type of test using a rooted MST is also presented for the multivariate two-sample problem.

MST and Multivariate Data Analysis

The goal of many multivariate data analytic techniques is to uncover interesting patterns and relationships in multivariate data (see **Multivariate Analysis: Overview**). In this direction, the MST has proved a useful tool for grouping objects into homogeneous groups, but also in visualizing the structure of multivariate data.

The presentation of Prim's algorithm in the section titled 'Applications of the MST' basically shows that the MST is essentially identical to the single linkage agglomerative hierarchical clustering algorithm [12] (see **Hierarchical Clustering**). By removing the $K - 1$ highest weight edges, one obtains a clustering solution with K groups [25]. An illustration of the MST as a clustering tool is given in Figure 7, where the first cluster corresponds to objects along a circular pattern and the second cluster to a square pattern inside the circle. It is worth noting that many popular clustering algorithms such as K-means and other agglomerative algorithms are going to miss the underlying group structure as the bottom right panel in Figure 7 shows.

The MST has also been used for identifying influential multivariate observations [15] (see **Multivariate Outliers**), for highlighting inaccuracies of low-dimensional representations of high-dimensional data through **multidimensional scaling** [3] and for visualizing structure in high dimensions [17] (see **k-means Analysis**).

Figure 7 A two-dimensional data example with two underlying clusters (top left panel), the corresponding MST (top right panel), the single linkage dendrogram (bottom left panel) and the average linkage dendrogram (bottom right panel)

The MST in Geometric Probability

The importance of the MST in many practical situations is that it determines the dominant skeleton structure of a point set by outlining the shortest path between nearest neighbors. Specifically, given a set of points $\mathcal{X}_n = \{x_1, x_2, \dots, x_n\}$ in $\mathbb{R}^d$ the MST $T(\mathcal{X}_n)$ connects all the points in the set by using as the weight function on the edges of the underlying complete graph the Euclidean distance. Steele [22] established that if the distances d_{ij} , $1 \leq i, j \leq n$ are independent and identically distributed with common cdf $F(d_{ij})$, then

$$\lim_{n \rightarrow \infty} \frac{T(\mathcal{X}_n)}{n^{\frac{d-1}{d}}} = \beta(d) \left(\frac{d-1}{d} \right)^{1/d}, \text{ a.s.} \quad (2)$$

where $\beta(d)$ is a constant that depends only on the dimension d . The above result is a variation on a theme in geometric probability pioneered by the celebrated paper of Bearwood et al. [2] on the length of the traveling salesman tour in Euclidean space. The exact value of the constant $\beta(d)$ is not known in general (see [1]).

The above result has provided a theoretical basis for using MSTs for image registration [18], for pattern recognition problems [24] and in assignment problems in wireless networks [4].

Concluding Remarks

An MST is an object that has attracted a lot of interest in graph and network theory. In this paper, we have also shown several of its uses in various areas of statistics and probability. Some other applications of MSTs have been in defining measures of multivariate association [10] (an extension of Kendall's τ measure) and more recently in estimating the intrinsic dimensionality of a nonlinear manifold from sparse data sampled from it [6].

Acknowledgments

The author would like to thank Jan de Leeuw and Brian Everitt for many useful suggestions and comments. This work was supported in part by NSF under grants IIS-9988095 and DMS-0214171 and NIH grant 1P41RR018627-01.

Misclassification Rates

Many situations arise in practice in which individuals have to be allocated into one of a number of prespecified classes. For example, applicants to a bank for a loan may be segregated into two groups: 'repayers' or 'defaulters'; a psychiatrist may have to decide whether a patient is suffering from depression or not, and if yes, then which of a number of types of depressive illness it is most likely to be; and applicants for employment in a company may be classified as being either 'suitable' or 'not suitable' for the position by an industrial psychologist. Rather than merely relying on subjective expert assessment in such cases, use is often made of quantitative predictions via mathematical or computational formulae, termed *allocation rules* or *classifiers*, which are based on a battery of relevant measurements taken on each individual. Thus, the bank manager might provide the classifier with information on each individual's financial circumstances as given, say, by his/her income, savings, number and size of existing loans, mortgage commitments, and so on, as well as concomitant information on such factors as nature of employment, marital status, educational level attained, and similar. The psychiatrist would perhaps supply information on the patient's responses to questions about levels of concentration, loss of sleep, feelings of inadequacy, stress at work, and ability to make decisions; while the industrial psychologist might use numerical scores assessing the subject's letter of application, previous educational attainments, performance at interview, level of ambition, and so on.

The construction of such classifiers has a long history, dating from the 1930s. Original application areas were in the biological and agricultural sciences, but the methods spread rapidly to the behavioral and social sciences and are now used widely in most areas of human activity. Many different forms of classifier have been suggested and currently exist, including simple combinations of measured variables as in the *linear discriminant function* and the *quadratic discriminant function* (see **Discriminant Analysis**), more complicated explicit functions such as the *logistic discriminant function* and *adaptive regression splines* (see **Logistic Regression**; **Scatterplot Smoothers**), implicitly defined functions, and 'black box' routines such as *feed-forward neural networks* (see **Neural Networks**), tree-based methods such

as *decision trees* or **classification and regression trees**, numerically based methods including ones based on *kernels*, *wavelets*, or *nearest neighbors*, and dimensionality-based techniques such as *support vector machines*. The methodology underlying the construction of these classifiers is described elsewhere (see **Discriminant Analysis**). We will simply assume that the form of classifier has been chosen in a particular application, and will focus on the assessment of efficacy of that classifier. Since the objective of classification is to allocate individuals to preexisting classes, and any classification must by its nature be subject to error, the most obvious measure of efficacy of a classifier is the proportion of individuals that it is likely to misclassify. Hence, the estimation of misclassification rates is an important practical consideration.

In any given application, there will be a set of observations available for individuals whose true class membership is known, from which the classifier is to be built; this is known as the *training set*. For example, the bank manager will have data on the chosen variables for a set of known defaulters, as well as for those who are known to have repaid their loans. Likewise, the psychiatrist will have measured the relevant variables for patients known to be suffering from each type of depressive illness as well as individuals who are not ill, and the industrial psychologist will have a similarly relevant data set available. Once the form of classifier has been chosen, these data are used to estimate its parameters; this is known as *training* the classifier.

As a specific example, consider a set of data originally given by Reaven and Miller [9]. These authors were interested in studying the relationship between chemical subclinical and overt nonketotic diabetes in nonobese adult subjects. The three primary variables used in the analysis were glucose intolerance (x_1), insulin response to oral glucose (x_2), and insulin resistance (x_3), and all subjects in the study were assigned by medical diagnosis to one of the three classes 'normal', 'chemical diabetic' and 'overt diabetic'. For illustrative purposes, we will use a simple linear discriminant function to distinguish the first and third classes, so our training set consists of the 76 normal and 33 overt diabetic subjects. The resulting trained classifier is $y = -21.525 + 0.023x_1 + 0.017x_2 + 0.015x_3$, and future patients can be assigned to one or other class according to their observed value of y .

2 Misclassification Rates

The problem now is to evaluate the (future) performance of such a trained classifier, and this can be done by estimating misclassification rates from each of the classes (i.e., the *class-conditional* misclassification rates). If the classifier has been constructed using a theoretical derivation from an assumed probability model, then there may be a theoretical expression available from which the misclassification rates can be estimated. For example, if we are classifying individuals into one of two groups, and we can assume that the measured variables follow multivariate normal distributions in the two groups, with mean vectors μ_1, μ_2 , respectively, and a common dispersion matrix Σ , then standard theory [7, p. 59] shows that the optimal classifier in terms of minimizing costs due to misclassification is the linear discriminant function used in the example above. Moreover, under the assumption of equal costs from each group and equal prior probabilities of each group, the probability of misclassifying an individual from each group by this function is $\Phi\{-1/2[\mu_1 - \mu_2]^T \Sigma^{-1}[\mu_1 - \mu_2]\}$ where $\mathbf{x}^T$ denotes the transpose of the vector $\mathbf{x}$ and $\Phi\{u\}$ is the integral of the standard normal density function between minus infinity and u . The parameters μ_1, μ_2 and Σ can be estimated by the group mean vectors and pooled within-groups **covariance matrix** of the training data, and substituting these values in the expression above will thus yield an estimate of the misclassification rates. Doing this for the diabetes example, we estimate the misclassification rate from each class to be 0.018.

However, estimation of the misclassification rates in this way is heavily dependent on the distributional assumptions made (whereas the classifier itself may be more widely applicable). For example, it turns out that a linear discriminant function is a useful classifier in many situations, even when the data do not come from normal populations, but the assumption of normality is critical to the above estimates of misclassification rates, and these estimates can be wrong when the data are not normally distributed. Moreover, there are many classifiers (e.g., neural networks, classification trees) for which appropriate probability models are very difficult if not impossible to specify. Hence, in general, reliance on distributional assumptions is dangerous and the training data must be used in a more direct fashion to estimate misclassification rates.

The most intuitive approach is simply to apply the classifier to all training set members in turn, and

to estimate the misclassification rates by the proportion of training set members from each group that are misclassified. This is known as the *resubstitution* method of estimation, and the resulting estimates are often called the *apparent* error rates. However, it can be seen easily that this is a biased method that will generally be overoptimistic (i.e., will underestimate the misclassification rates). This is because the classifier has itself been built from the training data and has utilized any differences between the groups in an optimal fashion, thereby minimizing as far as possible any misclassifications. Future individuals for classification may well lie outside the bounds of the training set individuals or have some different characteristics, and so misclassifications are likely to be more frequent. The smaller the available data set, the more will the classifier be tailored to it and, hence, the more extreme will be the difference in performance on future individuals. In this case, we say that the training data have been *overfitted* and the classifier has poor *generalization*.

The only way to ensure unbiased estimates of misclassification rates is to use different sets of data for forming and assessing the classifier. This can be achieved by having a training set for building the classifier, and then an independent *test set* (drawn from the same source) for estimating its misclassification rates. If the original training set is very large, then it can be randomly split into two portions, one of which forms the classifier training set and the other the test set. The proportions of individuals misclassified from each group of the test set then form the required estimates. The final classifier for future use is then obtained from the combined set. However, the process of dividing the data into two sets raises problems. If the training set is not very large, then the classifier being assessed may be poorly estimated, and may then differ considerably from the one finally used on future individuals; while if the test set is not very large, then the estimates of misclassification rates are subject to small-sample volatility and may not be reliable. Of course, if the data sets are huge, then the scope for overfitting the training data is small and resubstitution will give very similar results to test set estimation, and the problems do not arise. However, in many practical situations, the available data set is small to moderate in size, so resubstitution will not be reliable while splitting the set into training, and test sets is not viable. In these cases, we need something a little more ingenious, and **cross-validation**,

jackknifing, and **bootstrapping** are three data-based methods that have been proposed to fill the gap.

Cross-validation

Cross-validation aims to steer a middle ground between splitting the data into just one training and one test set, and using all the data for both building the classifier and assessing it. In this method, the data are divided into a number k of subsets; each subset is used in turn as the test set for a classifier constructed from the remainder of the data, and the proportions of misclassified individuals in each group when results from all k subsets have been combined give the estimates of misclassification rates. The final step is to build the classifier for future individuals from the full data set. This method was first introduced in [6] for the case $k = 1$, and this case is now commonly called the *leave-one-out* estimate of misclassification rates, while the general case is usually termed the *k-fold cross-validation* estimate. Clearly, if $k = 1$ and each individual is left out in turn, then the final classifier for future individuals will not differ much from the classifiers used to allocate each omitted individual, but a lot of computing may be necessary to complete the process. On the other hand, if k is quite large, then there is much less computing but more discrepancy between the classifiers obtained during the assessment procedure and the one used for future classifications. The leave-one-out estimator has been studied quite extensively, and has been shown to be approximately unbiased but to have large variance. Nevertheless, it is popular in applications. When k greater than 1 is preferred, then values around 6 to 10 are commonly used.

Jackknifing

The jackknife was originally introduced in [8] as a general way of reducing the bias of an estimator, and its application to misclassification rate estimation came later. It uses the same operations as the leave-one-out variant of cross-validation, but with a different purpose; namely, to reduce the bias of the resubstitution estimator. Let us denote by $e_{r,i}$ the resubstitution estimate of misclassification rate for group i as obtained from a classifier built from the whole training set. Suppose now that the j th individual is omitted from the data, a new classifier is built from

the reduced data set, and $e_{r,i}^{(j)}$ is the resubstitution estimate of misclassification rate for this classifier in group i . If this process is repeated, leaving out each of the n individuals in the data in turn, the average of the n resubstitution estimates of misclassification rate in group i (each based on a sample of size $n - 1$) can be found as $\bar{e}_{r,i} = 1/n \sum_j e_{r,i}^{(j)}$. Then the jackknife estimate of bias in $e_{r,i}$ is $(n - 1)(e_{r,i} - \bar{e}_{r,i})$ so that the corrected estimate becomes $e_{r,i} + (n - 1)(e_{r,i} - \bar{e}_{r,i})$. For some more details, and some relationships between this estimator and the leave-one-out estimator, see [2].

Bootstrapping

An alternative approach to removal of the bias in the resubstitution estimator is provided by bootstrapping. The basic bootstrap estimator works as follows. Suppose that we draw a sample of size n *with replacement* from the training data. This will have repeats of some of the individuals in the original data while others will be absent from it; it is known as a *bootstrap sample*, and it plays the role of a potential sample from the population from which the training data came. A classifier is built from the bootstrap sample and its resubstitution estimate of misclassification rate for group i is computed; denote this by $e_{r,i}^b$. If this classifier is then applied to the original training data and the proportion of misclassified group i individuals is computed as $e_{r,i}^{cb}$, then this latter quantity is an estimate of the ‘true’ misclassification rate for group i using the classifier from the bootstrap sample. The difference $d_b = e_{r,i}^{cb} - e_{r,i}^b$ is then an estimate of the bias in the resubstitution misclassification rate. To smooth out the vagaries of individual samples, we take a large number of bootstrap samples and obtain the average difference $\bar{d}$ over these samples; this is the bias correction to add to $e_{r,i}$.

The bootstrap has also been used for direct estimation of error rates. A number of ways of doing this have been proposed (see [1] for example), but one of the most successful is the so-called 632 bootstrap. In this method, the estimate of misclassification rate for group i is given by $0.368e_{r,i} + 0.632e_i$, where e_i is the proportion of all points *not* in each bootstrap sample that were misclassified for group i , and $e_{r,i}$ is the resubstitution estimate as before. The value 0.632 arises because it is equal to $1 - e^{-1}$, which is

the approximate probability that a specified individual will be selected for the bootstrap sample.

Tuning

The above methods are the ones currently recommended for estimating misclassification rates, but in some complex situations, they may become embedded in the classifier itself. This can happen for a number of reasons. One typical situation occurs when some parameters of the classifier have to be optimized by finding those values that minimize the misclassification rates; this is known as *tuning* the classifier. An example of this usage is in multilayer perceptron neural networks, where the training process is iterative and some mechanism is necessary for deciding when to stop. The obvious point at which to stop is the one at which the network performance is optimized, that is, the one at which its misclassification rate is minimized. If the training data set is sufficiently large, then the network is trained on one portion of it, the misclassification rates are continuously estimated from a second portion, and the training stops when these rates reach a minimum. Note, however, that quoting this achieved minimum rate as the estimate of future performance of the network would be incorrect, sometimes badly so. In effect, the same mistake would be made here as was made by using the resubstitution estimate in the ordinary classifier; the classifier has been trained to minimize the misclassifications on the second set of available data, so the minimum achieved rate is an overoptimistic assessment of how it will fare on future data. To obtain an unbiased estimate, we need a *third* (independent) set of data on which to assess the trained network. So, ideally, we need to divide our data into three: one set for training the data, one set to decide when training stops, and a third set to assess the final network. Many overoptimistic claims were made in the early days of development of neural networks because this point was not appreciated.

Variable Selection

A related problem occurs when variable selection is an objective of the analysis, whatever classifier is used. Typically, a set of variables is deemed to be optimal if it yields a minimum number of misclassifications. The same comments as above are relevant in

this situation also, and simply quoting this minimum achieved rate will be an overoptimistic assessment of future performance of these variables. However, if data sets are small, then an additional problem frequently encountered is that the estimation of misclassification rates for deciding on variable subsets is effected by means of the leave-one-out process. If this is the case, then an unbiased assessment of the overall procedure will require a *nested* leave-one-out process: each individual is omitted from the data in turn, and then the *whole procedure* is conducted on the remaining individuals. If this procedure involves variable selection using leave-one-out to choose the variables, then this must be done, and only when it is completed is the first omitted individual classified. Then the next individual is omitted and the whole procedure is repeated, and so on. Thus, considerably more computing needs to be done than at first meets the eye, but this is essential if unbiased estimates are to be obtained. Comparative studies showing the bias incurred when these procedures are sidestepped have been described in [3] for tuning and [4] for variable selection.

Note that in all the discussion above we have focused on estimation of the *class-conditional* misclassification rates. The *overall* misclassification rate of a classifier is given by a weighted average of the class-conditional rates, where the weights are the prior probabilities of the classes. Often, these prior probabilities have to be estimated. There is no problem if the training data have been obtained by random sampling of the whole population (i.e., *mixture sampling*), as the proportions of each class in the training data then yield adequate estimates of the prior probabilities. However, the proportions cannot be used in this way whenever the investigator has controlled the class sizes (*separate sampling*, as for example in case-control studies). In such cases, additional external information is generally needed for estimating prior probabilities.

A final matter to note is that all the estimates discussed above are *point* estimates, that is, single-value 'guesses' at the true error rate of a given classifier. Such point estimates will always be subject to sampling variability, so an *interval* estimate might give a more realistic representation. This topic has not received much attention, but a recent study [5] has looked at coverage rates of various intervals generated by standard jackknife, bootstrap, and cross-validation methods. The conclusion was that 632

bootstrap error rates plus jackknife-after-bootstrap estimation of their standard errors gave the most reliable confidence intervals.

To illustrate some of these ideas, consider the results from [5] on discriminating between the 76 normal subjects and the 33 subjects suffering from overt nonketotic diabetes using the linear discriminant function introduced above. All data-based estimates of misclassification rates differed from the normal-based estimates of 0.018 from each class, suggesting that the data deviate from normality to some extent. The apparent error rates were 0.000 and 0.061 for the two groups respectively, while the bootstrap 632 rates for these groups were 0.002 and 0.091. This illustrates the overoptimism typical of the resubstitution process, but the bootstrap error rates, nevertheless, seem to indicate that the classifier is a good one with less than a 10% chance of misallocating to the 'harder' group of diabetics. However, when the variability in estimation is taken into account and 90% confidence intervals are calculated from the bootstrap rates, we find intervals of (0.000, 0.012) for the normal subjects and (0.000, 0.195) for the diabetics. Hence, classification to the diabetic group could be much poorer than first thought.

The interested reader can find more detailed discussion of the above topics, with allied lists of references, in [2, 7].

Missing Data

Introduction

Missing values arise in behavioral science data for many reasons: **dropouts in longitudinal studies** (see **Longitudinal Data Analysis**), unit nonresponse in sample surveys where some individuals are not contacted or refusal to respond, refusal to answer particular items in a questionnaire, missing components in an index variable constructed by summing values of particular items. Missing data can also arise by design. For example, suppose one objective in a study of obesity is to estimate the distribution of a measure Y_1 of body fat in the population, and correlate it with other factors. Suppose Y_1 is expensive to measure but a proxy measure Y_2 , such as body mass index, which is a function of height and weight, is inexpensive to measure. Then it may be useful to measure Y_2 and covariates, X , for a large sample and Y_1 , Y_2 and X for a smaller subsample. The subsample allows predictions of the missing values of Y_1 to be generated for the larger sample, yielding more efficient estimates than are possible from the subsample alone.

Unless missing data are a deliberate feature of the study design, the most important step in dealing with missing data is to try to avoid it during the data-collection stage. Since data are still likely to be missing despite these efforts, it is important to try to collect covariates that are predictive of the missing values, so that an adequate adjustment can be made. In addition, the process that leads to missing values should be determined during the collection of data if possible, since this information helps to model the missing-data mechanism when an adjustment for the missing values is performed [2].

We distinguish three major approaches to the analysis of missing data:

1. Discard incomplete cases and analyze the remainder (complete-case analysis), as discussed in the section titled Complete-case, Available-case, and Weighting Analysis”;
2. Impute or fill in the missing values and then analyze the filled-in data, as discussed in the sections titled Single Imputation and Multiple Imputation;
3. Analyze the incomplete data by a method that does not require a complete (that is, a rectangular) data set, as discussed in the sections

titled Maximum Likelihood for Ignorable Models, Maximum Likelihood for Nonignorable Models, and Bayesian Simulation Methods.

A basic assumption in all our methods is that missingness of a particular value hides a true underlying value that is meaningful for analysis. This may seem obvious but is not always the case. For example, in a study of a behavioral intervention for people with heart disease, it is not meaningful to consider a quality of life measure to be missing for subjects who die prematurely during the course of the study. Rather, it is preferable to restrict the analysis to the quality of life measures of individuals who are alive.

Let $Y = (y_{ij})$ denote an $(N \times p)$ rectangular dataset without missing values, with i th row $y_i = (y_{i1}, \dots, y_{ip})$ where y_{ij} is the value of variable Y_j for subject i . With missing values, the *pattern* of missing data is defined by the *missing-data indicator matrix* $M = (m_{ij})$, such that $m_{ij} = 1$ if y_{ij} is missing and $m_{ij} = 0$ if y_{ij} is present. An important example of a special pattern is *univariate* nonresponse, where missingness is confined to a single variable. Another is *monotone* missing data, where the variables can be arranged so that $Y_{j+1}, \dots, Y_p$ are missing for all cases where Y_j is missing, for all $j = 1, \dots, p - 1$. This pattern arises commonly in longitudinal data subject to attrition, where once a subject drops out, no more data are observed. Some methods for handling missing data apply to any pattern of missing data, whereas other methods assume a special pattern.

The missing-data mechanism addresses the reasons why values are missing, and in particular, whether these reasons relate to values in the data set. For example, subjects in a longitudinal intervention may more likely to drop out of a study because they feel the treatment was ineffective, which might be related to a poor value of an outcome measure. Rubin [5] treated M as a random matrix, and characterized the missing-data mechanism by the conditional distribution of M given Y , say $f(M|Y, \phi)$, where ϕ denotes unknown parameters. Assume independent observations, and let m_i and y_i denote the rows of M and Y corresponding to individual i . When missingness for case i does not depend on the values of the data, that is,

$$f(m_i|y_i, \phi) = f(m_i|\phi) \quad \text{for all } y_i, \phi, \quad (1)$$

the data are called *missing completely at random* (MCAR). An MCAR mechanism is plausible in

2 Missing Data

planned missing-data designs, but is a strong assumption when missing data do not occur by design, because missingness often does depend on recorded variables. A less restrictive assumption is that missingness depends only on data that are observed, say $y_{\text{obs},i}$, and not on data that are missing, say $y_{\text{mis},i}$; that is,

$$f(m_i|y_i, \phi) = f(m_i|y_{\text{obs},i}, \phi) \quad \text{for all } y_{\text{mis},i}, \phi. \quad (2)$$

The missing-data mechanism is then called *missing at random* (MAR). Many methods for handling missing data assume the mechanism is MCAR, and yield biased estimates when the data are not MCAR. Better methods rely only on the MAR assumption.

Complete-case, Available-case, and Weighting Analysis

A common default approach is complete-case (CC) analysis, also known as *listwise* deletion, where incomplete cases are discarded and standard analysis methods applied to the complete cases [3, Section 3.2]. In many statistical packages, this is the default analysis. When the missing data are MCAR, the complete cases are a random subsample of the original sample, and CC analysis results in valid (but often inefficient) inferences. If the data are not MCAR then the complete cases are a biased sample, and CC analysis is often (though not always) biased, with a bias that depends on the degree of departure from MCAR, the amount of missing data, and the specifics of the analysis. The potential for bias is why sample surveys with high rates of unit nonresponse (say 30% or more) are often considered unreliable for making inferences to the whole population.

A modification of CC analysis, commonly used to handle unit nonresponse in surveys, is to weight respondents by the inverse of an estimate of the probability of response [3, Section 3.3]. A simple approach to estimation is to form adjustment cells (or subclasses) on the basis of background variables and weight respondents in an adjustment cell by the inverse of the response rate in that cell. This method eliminates bias if respondents within each adjustment cell respondents can be regarded as a random subsample of the original sample in that cell (i.e., the data are MAR given indicators for the

adjustment cells). A useful extension with extensive background information is *response propensity* stratification (see **Propensity Score**), where adjustment cells are based on similar values of estimates of probability of response, computed by a logistic regression of the indicator for missingness on the background variables. Although weighting methods can be useful for reducing nonresponse bias, they are potentially inefficient.

Available-case (AC) analysis [3, Section 3.4] is a straightforward attempt to exploit the incomplete information by using all the cases available to estimate each individual parameter. For example, suppose the objective is to estimate the correlation matrix of a set of continuous variables $Y_1, \dots, Y_p$. AC analysis uses all the cases with both Y_j and Y_k observed to estimate the correlation of Y_j and Y_k , $1 \leq j, k \leq p$. Since the sample base of available cases for measuring each correlation includes the set of complete cases, the AC method appears to make better use of available information. The sample base changes from correlation to correlation, however, creating potential problems when the missing data are not MCAR. In the presence of high correlations, AC can be worse than CC analysis, and there is no guarantee that the AC correlation matrix is even positive definite.

Single Imputation

Methods that impute or fill in the missing values have the advantage that, unlike CC analysis, observed values in the incomplete cases are retained. A simple version imputes missing values by their unconditional sample means based on the observed data, but this method often leads to biased inferences and cannot be recommended in any generality [3, Section 4.2.1]. An improvement is *conditional mean* imputation [3, Section 4.2.2], in which each missing value is replaced by an estimate of its conditional mean given the values of observed values. For example, in the case of univariate nonresponse with $Y_1, \dots, Y_{p-1}$ fully observed and Y_p sometimes missing, regression imputation estimates the regression of Y_p on $Y_1, \dots, Y_{p-1}$ from the complete cases, and the resulting prediction equation is used to impute the estimated conditional mean for each missing value of Y_p . For a general pattern of missing data, the missing values for each case can be imputed from the regression of the missing variables on the observed

variables, computed using the set of complete cases. Iterative versions of this method lead (with some important adjustments) to maximum likelihood estimates under multivariate normality [3, Section 11.2].

Although conditional mean imputation yields best predictions of the missing values in the sense of mean squared error, it leads to distorted estimates of quantities that are not linear in the data, such as percentiles, variances, and correlations. A solution to this problem is to impute random draws from the predictive distribution rather than best predictions. An example is *stochastic regression* imputation, in which each missing value is replaced by its regression prediction plus a random error with variance equal to the estimated residual variance. Another approach is *hot-deck* imputation, which classifies respondents and nonrespondents into adjustment cells based on similar values of observed variables and then imputes values for nonrespondents from randomly chosen respondents in the same cell. A more general approach to hot-deck imputation matches nonrespondents and respondents using a distance metric based on the observed variables. For example, *predictive mean matching* imputes values from cases that have similar predictive means from a regression of the missing variable on observed variables. This method is somewhat robust to misspecification of the regression model used to create the matching metric [3, Section 4.3].

The imputation methods discussed so far assume the missing data are MAR. In contrast, models that are not missing at random (NMAR) assert that even if a respondent and nonrespondent to Y_p appear identical with respect to observed variables $Y_1, \dots, Y_{p-1}$, their Y_p -values differ systematically. A crucial point about the use of NMAR models is that there is never direct evidence in the data to address the validity of their underlying assumptions. Thus, whenever NMAR models are being considered, it is prudent to consider several NMAR models and explore the sensitivity of analyses to the choice of model [3, Chapter 15].

Multiple Imputation

A serious defect with imputation is that a single imputed value cannot represent the uncertainty about, which value to impute, so analyses that treat imputed values just like observed values generally underestimate uncertainty, even if nonresponse is modeled

correctly. **Multiple imputation** (MI, [6, 7]) fixes this problem by creating a set of Q (say $Q = 5$ or 10) draws for each missing value from a predictive distribution, and thence Q datasets, each containing different sets of draws of the missing values. We then apply the standard complete-data analysis to each of the Q datasets and combine the results in a simple way. In particular, for scalar estimands, the MI estimate is the average of the estimates from the Q datasets, and the variance of the estimate is the average of the variances from the five datasets plus $1 + 1/Q$ times the sample variance of the estimates over the Q datasets (The factor $1 + 1/Q$ is a small- Q correction). The last quantity here estimates the contribution to the variance from imputation uncertainty, missed (i.e., set to zero) by single imputation methods. Another benefit of multiple imputation is that the averaging over datasets results in more efficient point estimates than does single random imputation. Often, MI is not much more difficult than doing a single imputation – the additional computing from repeating an analysis Q times is not a major burden and methods for combining inferences are straightforward. Most of the work is in generating good predictive distributions for the missing values.

Maximum Likelihood for Ignorable Models

Maximum likelihood (ML) avoids imputation by formulating a statistical model and basing inference on the likelihood function of the incomplete data [3, Section 6.2]. Define Y and M as above, and let X denote an $(n \times q)$ matrix of fixed covariates, assumed fully observed, with i th row $x_i = (x_{i1}, \dots, x_{iq})$ where x_{ij} is the value of covariate X_j for subject i . Covariates that are not fully observed should be treated as random variables and modeled with the set of Y_j 's.

Two likelihoods are commonly considered. The *full* likelihood is obtained by integrating the missing values out of the joint density of Y and M given X . The *ignorable* likelihood is obtained by integrating the missing values out of the joint density of Y given X , ignoring the distribution of M . The ignorable likelihood is easier to work with than the full likelihood, since it is easier to handle computationally, and more importantly because it avoids the need to specify a model for the missing-data mechanism, about

which little is known in *many situations*. Rubin [5] showed that valid inferences about parameters can be based on the ignorable likelihood when the data are MAR, as defined above. (A secondary condition, *distinctness*, is needed for these inferences to be fully efficient). Large-sample inferences about parameters can be based on standard ML theory [3, Chapter 6].

In many problems, maximization of the likelihood requires numerical methods. Standard optimization methods such as Newton–Raphson or Scoring can be applied. Alternatively, we can apply the *Expectation–Maximization (EM)* algorithm [1] or one of its extensions [3, 4]. Reference [3] includes many applications of EM to particular models, including normal and t models for multivariate continuous data, **log-linear models** for multiway contingency tables, and the general location model for mixtures of continuous and categorical variables. Asymptotic standard errors are not readily available from EM, unlike numerical methods like scoring or Newton–Raphson. A simple approach is to use the **bootstrap** or the **jackknife** method [3, Chapter 5]. An alternative is to switch to a Bayesian simulation method that simulates the posterior distribution of the parameters (see the section titled Bayesian Simulation Methods).

Maximum Likelihood for Nonignorable Models

Nonignorable, non–MAR models apply when missingness depends on the missing values (see the section titled Introduction). A correct likelihood analysis must be based on the full likelihood from a model for the joint distribution of Y and M . The standard likelihood asymptotics apply to nonignorable models providing the parameters are identified, and computational tools such as EM also apply to this more general class of models. However, often information to estimate both the parameters of the missing-data mechanism and the parameters of the complete-data model is very limited, and estimates are sensitive to misspecification of the model. Often, a **sensitivity analysis** is needed to see how much the answers change for various assumptions about the missing-data mechanism [[3], Chapter 15].

Bayesian Simulation Methods

Maximum likelihood is most useful when sample sizes are large, since then the log-likelihood is nearly

quadratic and can be summarized well using the ML estimate θ and its large sample variance–covariance matrix. When sample sizes are small, a useful alternative approach is to add a prior distribution for the parameters and compute the posterior distribution of the parameters of interest. Since the posterior distribution rarely has a simple analytic form for incomplete-data problems, simulation methods are often used to generate draws of θ from the posterior distribution $p(\theta|Y_{obs}, M, X)$. Data augmentation [10] is an iterative method of simulating the posterior distribution of θ that combines features of the EM algorithm and multiple imputation, with Q imputations of each missing value at each iteration. It can be thought of as a small-sample refinement of the EM algorithm using simulation, with the imputation step corresponding to the E-step (random draws replacing expectation) and the posterior step corresponding to the M-step (random draws replacing MLE). When Q is set equal to one, data augmentation is a special case of the Gibbs’ sampler. This algorithm can be run independently Q times to generate M iid draws from the approximate joint posterior distribution of the parameters and the missing data. The draws of the missing data can be used as multiple imputations, yielding a direct link with the methods in the section titled Multiple Imputation.

Conclusion

In general, the advent of modern computing has made more principled methods of dealing with missing data practical, such as multiple imputation (e.g. PROC MI in [8]) or ignorable ML for repeated measures with dropouts (see **Dropouts in Longitudinal Studies: Methods of Analysis**). See [3] or [9] to learn more about missing-data methodology.

Model Based Cluster Analysis

Many methods of cluster analysis are based on *ad hoc* ‘sorting’ algorithms rather than some sound statistical model (see **Hierarchical Clustering; *k*-means Analysis**). This makes it difficult to evaluate and assess solutions in terms of a set of explicit assumptions. More statistically respectable are model-based methods in which an explicit model for the clustering process is specified, containing parameters defining the characteristics of the assumed clusters. Such an approach replaces ‘sorting’ with estimation and may lead to formal

tests of cluster structure, particularly for **number of clusters**.

The most well-known type of model-based clustering procedure uses **finite mixture distributions**. Other possibilities are described in [2] and include the classification likelihood approach [1] and **latent class analysis**.

Model Evaluation

Introduction

The main reason for building models is to link theoretical ideas to observed data, and the central question that we are interested in is ‘Is the model any good’? When dealing with quantitative models, we can at least partially answer this question using statistical tools. Before going into detail, there is a touchy, even philosophical, issue that one cannot ignore. A naive view of modeling is to identify the underlying process (truth) that has actually generated the data. This is an ill-posed problem, meaning that the solution is nonunique. The finite data sample rarely contains sufficient information to lead to a single process and also, is corrupted by unavoidable random noise, blurring the identification. An implication of noise-corrupted data is that it is not in general possible to determine with complete certainty that what we are fitting is the regularity, which we are interested in, or the noise, which we are not. A model that assumes a certain amount of error is present may be worse than a yet to be postulated model that can explain more of what we thought of as error in the first model. In short, identifying the true model based on data samples is an unachievable goal. Furthermore, the ‘truth’ of any phenomenon is likely to be rather different from any proposed model. Ultimately, it is crucial to recognize that *all* models are wrong, and a realistic goal of modeling is to find a model that represents a ‘good’ approximation to the truth in a statistically defined sense.

In what follows, we assume that we have a model $\mathcal{M}$ with k free parameters $\theta = (\theta_1, \dots, \theta_k)$, and a data set that consists of n observations $X = (X_1, \dots, X_n)$. Quantitative models generally come in two main types: They either assign some probability to the observed data $f(X|\theta)$ (probabilistic models), or they produce a single predicted data set $X^{prd}(\theta)$ (deterministic models). We should note that most model testing and model selection methods require a probabilistic formulation, so it is commonplace to define a model as $\mathcal{M} = \{f(X|\theta) | \theta \in \Omega\}$ where Ω is the parameter space. When written in this form, a model can be conceptualized as a family of probability distributions.

Model Fitting

At a minimum, any reasonable model needs to be able to mimic the structure of the data: It needs to be able to ‘fit’ the data. When measuring the goodness of a model’s fit, we find the parameter values that allow the model to best mimic the data, denoted $\hat{\theta}$. The two most common methods for this are **maximum likelihood estimation** (for probabilistic models) and **least squares estimation** (for deterministic models). In the maximum likelihood approach, introduced by **Sir Ronald Fisher** in the 1920s, $\hat{\theta}$ is the set of parameter values that maximizes $f(X|\theta)$, and is referred to as the maximum likelihood estimate (MLE). The corresponding measure of fit is the maximized log-likelihood $\hat{L} = \ln f(X|\hat{\theta})$. See [3] for a tutorial on maximum likelihood estimation with example applications in cognitive psychology.

Alternatively, the least squares estimate of $\hat{\theta}$ is the set of parameters that minimizes the *sum of squared errors* (SSE), and the minimized SSE value is denoted by $\hat{E}$:

$$\hat{E} = \sum_{i=1}^n (X_i - X_i^{prd}(\hat{\theta}))^2. \quad (1)$$

When this approach is employed, there are several commonly used measures of fit. They are *mean-squared error* $MSE = \hat{E}/n$, *root mean-squared deviation* $RMSD = \sqrt{(\hat{E}/n)}$, and *squared correlation* (also known as proportion of variance accounted for) $r^2 = 1 - \hat{E}/SST$. In the last formula, SST stands for the *sum of squares total* defined as $SST = \sum_{i=1}^n (X_i - \bar{X})^2$, where $\bar{X}$ denotes the mean of X . There is a nice correspondence between maximum likelihood and least squares, in that for a model with independent, identically and normally distributed errors, the same set of parameters is obtained as the one that maximizes the log-likelihood L but also minimizes the sum of squared errors SSE .

Model fitting yields goodness-of-fit measures, such as $\hat{L}$ or $\hat{E}$, that tell us how well the model fits the observed data sample but by themselves are not particularly meaningful. If our model has a minimized sum squared error of 0.132, should we be impressed or not? In other words, a goodness-of-fit measure may be useful as a purely descriptive measure, but by itself is not amenable to statistical inference. This is because the measure does not address the relevant

2 Model Evaluation

question: ‘Does the model provide an *adequate* fit to the data, in a defined sense’?. This question is answered in model testing.

Model Testing

Classical null hypothesis testing is a standard method of judging a model’s goodness of fit. The idea is to set up a null hypothesis that ‘the model is correct’, obtain the P value, and then make a decision about rejecting or retaining the hypothesis by comparing the resulting P value with the alpha level.

For discrete data such as frequency counts, the two most popular methods are the Pearson chi-square (χ^2) test and the log-likelihood ratio test (G^2), which have test statistics given by

$$\begin{aligned}\chi^2 &= \sum_{i=1}^n \frac{(X_i - X_i^{prd}(\hat{\theta}))^2}{X_i^{prd}(\hat{\theta})}; \\ G^2 &= -2 \sum_{i=1}^n X_i \ln \frac{X_i^{prd}(\hat{\theta})}{X_i},\end{aligned}\quad (2)$$

where $\ln$ is the natural logarithm of base e . Both of these statistics have the nice property that they are always nonnegative, and are equal to zero when the observed and predicted data are in full agreement. In other words, the larger the statistic, the greater the discrepancy. Under the null hypothesis, both are approximately distributed as a χ^2 distribution with $(n - k - 1)$ degrees of freedom, so we would reject the null if the obtained P value is larger than some critical value obtained by setting an appropriate α level.

For continuous data such as response time, goodness-of-fit tests are a little more complicated, since there are no general-purpose methods available for testing the validity of a single model, unlike the discrete case. Instead, we rely on the *generalized likelihood ratio test* that involves two models. In this test, in addition to the theoretically motivated model, denoted by $\mathcal{M}_r$ (reduced model), we create a second model, $\mathcal{M}_f$ (full model), such that the reduced model is obtained as a special case of the full model by fixing one or more of $\mathcal{M}_f$ ’s parameters. Then, the goodness of fit of the reduced model is assessed by the following G^2 statistic:

$$G^2 = 2(\ln \hat{L}_f - \ln \hat{L}_r), \quad (3)$$

recalling that $\hat{L}$ denotes the maximized log-likelihood. Under the null hypothesis that the theoretically motivated, reduced model is correct, the above statistic is approximately distributed as χ^2 with degrees of freedom given by the difference in the number of parameters ($k_f - k_r$). If the hypothesis is retained (rejected), then we conclude that the reduced model $\mathcal{M}_r$ provides (does not provide) an adequate description of the data (see [4] for an example application of this test).

Model Selection

What does it mean that a model provides an adequate fit of the data? One should not jump to the conclusion that one has identified the underlying regularity. A good fit merely puts the model on a list of candidate models worthy of further consideration. It is entirely possible that there are several distinct models that fit the data well, all passing goodness of fit tests. How should we then choose among such models? This is the problem of model selection.

In model selection, the goal is to select the one, among a set of candidate models, that represents the closest approximation to the underlying process in some defined sense. Choosing the model that best fits a particular set of observed data will not accomplish the goal. This is because a model can achieve a superior fit to its competitors for reasons unrelated to the model’s exactness. For instance, it is well known that a complex model with many parameters and highly nonlinear form can often fit data better than a simple model with few parameters even if the latter generated the data. This is called *overfitting*.

Avoiding overfitting is what every model selection method is set to accomplish. The essential idea behind modern model selection methods is to recognize that, since data are inherently noisy, an ideal model is one that captures only the underlying phenomenon, not the noise. Since noise is idiosyncratic to a particular data set, a model that captures noise will make poor predictions about future events. This leads to the present-day ‘gold standard’ of model selection, **generalizability**. Generalizability, or predictive accuracy, refers to a model’s ability to predict the statistics of future, as yet unseen, data samples from the same process that generated the observed data sample.

The intuitively simplest way to measure generalizability is to estimate it directly from the data, using

cross-validation (CV; [10]). In cross-validation, we split the data set into two samples, the calibration sample X_c and the test sample X_t . We first estimate the best-fitting parameters by fitting the model to X_c which we denote $\hat{\theta}(X_c)$. The generalizability estimate is obtained by measuring the fit of the model to the test sample at those original parameters, that is, $\hat{\theta}(X_c)$,

$$CV = \ln f(X_t | \hat{\theta}(X_c)). \quad (4)$$

The main attraction of CV is its ease of implementation (see [4] for its application example for psychological models). All that is required is a model fitting procedure and a resampling scheme. One concern with CV is that there is a possibility that the test sample is not truly independent of the calibration sample: Since both were produced in the same experiment, systematic sources of error variation are likely to induce correlated noise across the two samples, artificially inflating the CV measure.

An alternative approach is to use theoretical measures of generalizability based on a single sample. In most of these theoretical approaches, generalizability is measured by suitably combining goodness-of-fit with model complexity. The practical difference between them is the way in which complexity is measured. One of the earliest measures of this kind was the **Akaike information criterion** (AIC; [1]), which treats complexity as the number of parameters k :

$$AIC = -2 \ln f(X | \hat{\theta}) + 2k, \quad (5)$$

The method prescribes that the model minimizing AIC should be chosen. AIC seeks to find the model that lies ‘closest’ to the true distribution, as measured by the Kullback–Leibler [8] discrepancy. As shown in the above criterion equation, this is achieved by trading the first, minus goodness-of-fit (lack of fit) term of the right hand side for the second complexity term. As such, a complex model with many parameters, having a large value of the complexity term, will not be selected unless its fit justifies the extra complexity. In this sense, AIC represents a formalization of the principle of Occam’s razor, which states ‘Entities should not be multiplied beyond necessity’ (William of Occam, ca. 1290–1349) (see **Parsimony/Occam’s Razor**).

Another approach is given by the much older notion of **Bayesian statistics**. In the Bayesian approach, we assume that *a priori* uncertainty about

the value of model parameters is represented by a prior distribution $\pi(\theta)$. Upon observing the data X , this prior is updated, yielding a posterior distribution $\pi(\theta | X) \propto f(X | \theta) \pi(\theta)$. In order to make inferences about the model (rather than its parameters), we integrate across the posterior distribution. Under the assumption that all models are *a priori* equally likely (because the Bayesian approach requires model priors as well as parameter priors), Bayesian model selection chooses the model $\mathcal{M}$ with highest marginal likelihood defined as:

$$f(X | \mathcal{M}) = \int f(X | \theta) \pi(\theta) d\theta. \quad (6)$$

The ratio of two marginal likelihoods is called a *Bayes factor* (BF; [2]), which is a widely used method of model selection in Bayesian inference. The two integrals in the Bayes factor are nontrivial to compute unless $f(X | \theta)$ and $\pi(\theta)$ form a conjugate family. Monte Carlo methods are usually required to compute BF, especially for highly parameterized models (see **Markov Chain Monte Carlo and Bayesian Statistics**). A large sample approximation of BF yields the easily computable Bayesian information criterion (BIC; [9])

$$BIC = -2 \ln f(X | \hat{\theta}) + k \ln n. \quad (7)$$

The model minimizing BIC should be chosen. It is important to recognize that the BIC is based on a number of restrictive assumptions. If these assumptions are met, then the difference between two BIC values approaches twice the logarithm of the Bayes factor as n approaches infinity.

A third approach is minimum description length (MDL; [5]), which originates in algorithmic coding theory. In MDL, a model is viewed as a code that can be used to compress the data. That is, data sets that have some regular structure can be compressed substantially if we know what that structure is. Since a model is essentially a hypothesis about the nature of the regularities that we expect to find in data, a good model should allow us to compress the data set effectively. From an MDL standpoint, we choose the model that permits the greatest compression of data in its total description: That is, the description of data obtainable with the help of the model plus the description of the model itself. A series of papers by Rissanen expanded on and refined this idea, yielding a number of different model selection criteria (one

of which was essentially identical to the BIC). The most complete MDL criterion currently available is the *stochastic complexity* (SC; [7]) of the data relative to the model,

$$SC = -\ln f(X|\hat{\theta}) + \ln \int f(Y|\hat{\theta}(Y)) dY. \quad (8)$$

Note that the second term of SC represents a measure of model complexity. Since the integral over the sample space is generally nontrivial to compute, it is common to use the Fisher-information approximation (FIA; [6]): Under regularity conditions, the stochastic complexity asymptotically approaches

$$FIA = -\ln f(X|\hat{\theta}) + \frac{k}{2} \ln \left(\frac{n}{2\pi} \right) + \ln \int_{\Theta} \sqrt{\det I(\theta)} d\theta, \quad (9)$$

where $I(\theta)$ is the expected Fisher **information matrix** of sample size one, consisting of the covariances between the partial derivatives of L with respect to the parameters. Once again, the integral can still be intractable, but it is generally easier to calculate than the exact SC. As in AIC and BIC, the first term of FIA is the lack of fit term and the second and third terms together represent a complexity measure. From the viewpoint of FIA, complexity is determined by the number of free parameters (k) and sample size (n) but also by the ‘functional form’ of the model equation, as implied by the Fisher information $I(\theta)$, and the range of the parameter space Θ .

When using generalizability measures, it is important to recognize that AIC, BIC, and FIA are all *asymptotic* criteria, and are only guaranteed to work as n becomes arbitrarily large, and when certain regularity conditions are met. The AIC and BIC, in particular, can be misleading for small n . The FIA is safer (i.e., the error level generally falls faster as n increases), but it too can still be misleading in some cases. The SC and BF criteria are more sensitive, since they are exact rather than asymptotic criteria, and can be quite powerful even when presented with very similar models or small samples. However, they can be difficult to employ, and often need to be approximated numerically. The status of CV is a little more complicated, since it is not always clear what CV is doing, but its performance in practice is often better than AIC or BIC, though it is not usually as good as SC, FIA, or BF.

Conclusion

When evaluating a model, there are a number of factors to consider. Broadly speaking, statistical methods can be used to measure the descriptive adequacy of a model (by fitting it to data and testing those fits), as well as its generalizability and simplicity (using model selection tools). However, the strength of the underlying theory also depends on its interpretability, its consistency with other findings, and its overall plausibility. These things are inherently subjective judgments, but they are no less important for that. As always, there is no substitute for thoughtful evaluations and good judgment. After all, statistical evaluations are only one part of a good analysis.

Model Fit: Assessment of

Introduction

Item response theory (IRT) models (*see* **Item Response Theory (IRT) Models for Dichotomous Data**) provide a useful and well-founded framework for measurement in the social sciences. However, the applications of these models are only valid if the model fits the data. IRT models are based on a number of explicit assumptions, so methods for the evaluation of model fit focus on these assumptions. Model fit can be viewed from two perspectives: the items and the respondents. In the first case, for every item, residuals (differences between predictions from the estimated model and observations) and item fit statistics are computed to assess whether the item violates the model. In the second case, residuals and person-fit statistics are computed for every person to assess whether the responses to the items follow the model.

The most important assumptions evaluated are subpopulation invariance (the violation is often labeled **differential item functioning**), the form of the item response function, and local stochastic independence. The first assumption entails that the item responses can be described by the same parameters in all possible subpopulations. Subpopulations are defined on the basis of background variables that should not be relevant in a specific testing situation. One might think of gender, race, age, or socioeconomic status. The second assumption addressed is the form of the item response function that describes the relation between a **latent variable**, say proficiency, and observable responses to items. Evaluation of the appropriateness of the item response function is usually done by comparing observed and expected item response frequencies given some measure of the latent trait level. The third assumption targeted is local stochastic independence. The assumption entails that responses to different items are independent given the latent trait value. So the proposed latent variables completely describe the responses and no additional variables are necessary to describe the responses.

A final remark in this introduction pertains to the relation between formal tests of model fit and residual analyses. A well-known problem with formal tests of model fit is that they tend to reject the model even

for moderate sample sizes. That is, their **power** (the probability of rejection when the model is violated) grows very fast as a function of the sample size. As a result, small deviations from the IRT model may cause a rejection of the model while these deviations may hardly have practical consequences in the foreseen application of the model. Inspection of the magnitude of the residuals can shed light on the severity of the model violation. The reason for addressing problem of evaluation of model fit in the framework of formal model tests is that the alternative hypotheses in these model tests clarify which model assumptions are exactly targeted by the residuals. This will be explained further below.

We will start with describing evaluation of fit to IRT models for dichotomous items, then a general approach to evaluation of model fit for a general class of IRT models will be outlined, and finally, a small example will be given. The focus will be on parameterized IRT models in a likelihood-based framework. The relation with other approaches to IRT will be briefly sketched in the conclusion.

Assessing Model Fit for Items with Dichotomous Responses

In the 1-, 2-, and 3-parameter logistic models (1PLM, 2PLM and 3PLM), [2] it is assumed that the proficiency level of a respondent (indexed i) can be represented by a one-dimensional proficiency parameter θ_i . In the 3PLM, the probability of a correct response as a function of θ_i is given by

$$\begin{aligned} \Pr(Y_{ik} = 1 | \theta_i, a_k, b_k, c_k) \\ = P_k(\theta_i) = c_k + (1 - c_k) + \frac{\exp(a_k(\theta_i - b_k))}{1 + \exp(a_k(\theta_i - b_k))}, \end{aligned} \quad (1)$$

where Y_{ik} is a random variable assuming a value equal to one if a correct response was given to item k , and zero otherwise. The three item parameters, a_k , b_k , and c_k are called the *discrimination*, *difficulty* and *guessing parameter*, respectively. The 2PLM follows upon setting the guessing parameter c_k equal to zero, and the 1PLM follows upon introducing the additional constraint $a_k = 1$.

2 Model Fit: Assessment of

Testing the Form of the Item Characteristic Function

Ideally, a test of the fit of the item response function $P_k(\theta_i)$ would be based on assessing whether the proportion of correct responses to item k of respondents with a proficiency level θ^* matches $P_k(\theta^*)$. In the 2PLM and 3PLM this has the problem that the estimates of the proficiency parameters are virtually unique, so for every available θ -value there is only one observed response on item k available. As a result, we cannot meaningfully compute proportions of correct responses given a value of θ . However, the number-correct scores and the estimates of θ are usually highly correlated, and, therefore, tests of model fit can be based on the assumption that groups of respondents with the same number-correct score will probably be quite homogeneous with respect to their proficiency level. So a broad class of test statistics has the form

$$Q_1 = \sum_{r=1}^{K-1} N_r \frac{(O_{rk} - E_{rk})^2}{E_{rk}(1 - E_{rk})}, \quad (2)$$

where K is the test length, N_r is the number of respondents obtaining a number-correct score r , O_{rk} is the proportion of respondents with a score r and a correct score on item k , and E_{rk} is the analogous probability under the IRT model. Examples of statistics of this general form are a statistic proposed by Van den Wollenberg [25] for the 1PLM in the framework of (conditional maximum likelihood estimation) CML estimation and a test statistic for the 2PLM and 3PLM proposed by Orlando and Thissen [13] in the framework of (marginal maximum likelihood) MML estimation. For details on the computation of these statistics see [13] and [25] (*see Maximum Likelihood Estimation*).

Simulation studies show that the Q_1 -statistic is well approximated by a χ^2 -distribution [7, 22].

For long tests, it would be practical when a number of adjacent scores could be combined, say to obtain 4 to 6 score-level groups. So the sum over number-correct scores r would be replaced by a sum over score-levels g ($g = 1, \dots, G$) and the test would be based on the differences $O_{gk} - E_{gk}$. Unfortunately, it turns out that the variances of these differences cannot be properly estimated using an expression analogous to the denominator of Formula (2). The problem of weighting the differences $O_{gk} - E_{gk}$ with a proper

estimate of their variance (and covariance) will be returned to below.

Differential Item Functioning

Differential item functioning (DIF) is a difference in item responses between equally proficient members of two or more groups. One might think of a test of foreign language comprehension, where items referring to football might impede girls. The poor performance of the girls on the football-related items must not be attributed to their low proficiency level but to their lack of knowledge of football. Since DIF is highly undesirable in fair testing, methods for the detection of DIF are extensively studied. Several techniques for detection of DIF have been proposed. Most of them are based on evaluation of differences in response probabilities between groups conditional on some measure of proficiency. The most generally used technique is based on the **Mantel-Haenszel (MH) statistic** [9]. In this approach, the respondent's number-correct score is used as a proxy for proficiency, and DIF is evaluated by testing whether the response probabilities differ between the score groups. In an IRT model, proficiency is represented by a latent variable θ , and DIF can be assessed in the framework of IRT by evaluating whether the same item parameters apply in subgroups (say subgroups $g = 1, \dots, G$) that are homogeneous with respect to θ . This is achieved by generalizing the test statistic in Formula (2) to

$$Q_1 = \sum_{g=1}^G \sum_{r=1}^{K-1} N_{gr} \frac{(O_{grk} - E_{grk})^2}{E_{grk}(1 - E_{grk})}, \quad (3)$$

where N_{gr} is the number of respondents obtaining a number-correct score r in subgroup g , and O_{grk} and E_{grk} are the observed proportion and estimated probability for that combination of h and r .

Combination of number-correct scores has similar complications as discussed above, so this problem will also be addressed in the last section.

Testing Local Independence and Multidimensionality

The statistics of the previous section can be used for testing whether the data support the form of the item response functions. Another assumption underlying the IRT models presented above is unidimensionality.

Suppose unidimensionality is violated. If the respondent's position on one latent trait is fixed, the assumption of local stochastic independence requires that the association between the items vanishes. In the case of more than one dimension, however, the respondent's position in the latent space is not sufficiently described by one one-dimensional proficiency parameter and, as a consequence, the association between the responses to the items given this one proficiency parameter will not vanish. Therefore, tests for unidimensionality are based on the association between the items.

Van den Wollenberg [25] and Yen [26, 27] show that violation of local independence can be tested using a test statistic based on the evaluation of the association between items in a 2-by-2 table. Applying this idea to the 3PLM in an MML framework, a statistic can be based on the difference between observed and expected frequencies given by

$$\begin{aligned} d_{kl} &= n_{kl} - E(N_{kl}) \\ &= n_{kl} - \sum_{r=2}^{K-1} n_r P(Y_k = 1, Y_l = 1 | R = r), \end{aligned} \quad (4)$$

where n_{kl} is the observed number of respondents making item k and item l correct, in the group of respondents obtaining a score between 2 and $K-2$, and $E(N_{kl})$ is its expectation. Only scores between 2 and $K-2$ are considered, because respondents with a score less than 2 cannot make both items correct, and respondents with a score greater than $K-2$ cannot make both items incorrect. So these respondents contribute no information to the 2-by-2 table. Using Pearson's X^2 -statistic for association in a 2-by-2 table results in

$$S_{3kl} = \frac{d_{kl}^2}{E(N_{kl})} + \frac{d_{kl}^2}{E(N_{k\bar{l}})} + \frac{d_{kl}^2}{E(N_{\bar{k}l})} + \frac{d_{kl}^2}{E(N_{\bar{k}\bar{l}})}, \quad (5)$$

where $E(N_{kl})$ is the expectation of making item k correct and l wrong, and $E(N_{k\bar{l}})$ and $E(N_{\bar{k}l})$ are defined analogously. Simulation studies by Glas and Suárez-Falcón (2003) show that this statistic is well approximated by a χ^2 -distribution with one degree of freedom.

Person Fit

In the previous sections, item fit was investigated across respondents. Analogously, fit of respondents

can be investigated across items. Usually, investigation of item fit precedes the investigation of person fit, but evaluation of item and person fit can also be an iterative process. Person fit is used to check whether a person's pattern of item responses is unlikely given the model. Unlikely response patterns may occur because respondents are unmotivated or unable to give proper responses that relate to the relevant proficiency variable, or because they have preknowledge of the correct answers, or because they are cheating.

As an example we will consider a person fit statistic proposed by Smith [19]. The set of test items is divided into G nonoverlapping subtests denoted A_g ($g = 1, \dots, G$) and the test is based on the discrepancies between the observed scores and the expected scores under the model summed within subsets of items. That is, the statistic is defined as

$$UB = \frac{1}{G-1} \sum_{g=1}^G \frac{\left[\sum_{k \in A_g} (y_k - P_k(\theta)) \right]^2}{\sum_{k \in A_g} P_k(\theta)(1 - P_k(\theta))} \quad (6)$$

Since the statistic is computed only for individual students, the index i was dropped. One of the problems of this statistic is that its distribution under the null-hypothesis cannot be derived because the effects of the estimation of the parameters are not taken into account. Snijders [20] proposed a correction-factor that solves this problem.

Polytomous Items and Multidimensional Models

In the previous section, assessment of fit to IRT models was introduced by considering one-dimensional IRT models for dichotomously scored items. In this section, we will consider a more general framework, where items are scored polytomously (with dichotomous scoring as a special case) and where the latent proficiency can be multidimensional. In polytomous scoring the response to an item k can be in one of the categories $j = 0, \dots, M_k$. In one-dimensional IRT models for polytomous items, it is assumed that the probability of scoring in an item category depends on a one-dimensional latent variable θ . An example of the category response functions for an item with

Figure 1 Response functions of a polytomously scored item

four ordered response categories is given in Figure 1. Note that the forms of the response functions are plausible for proficiency items: the response function of the zero-category decreases as a function of proficiency, the response function for the highest category increases with proficiency, and the response functions for the intermediate categories are single-peaked.

Item response models giving rise to response functions as in Figure 1 fall into three classes [11]: adjacent-category models [10], continuation-ratio models [24] and cumulative probability models [18]. The rationales underlying the models are very different but the shapes of their response functions are very similar. As an example, we give a model in the first class, the generalized partial credit model (GPCM) by Muraki [12]. The probability of a student i scoring in category j on item k given by

$$p(Y_{ikj} = 1|\theta_i) = \frac{\exp(ja_k\theta_i - b_{kj})}{1 + \sum_{h=1}^{M_k} \exp[ha_k\theta_i - b_{kh}]}, \quad (7)$$

where Y_{ikj} is a random variable assuming a value one if a response was given in category j ($j = 1, \dots, M_k$), and assuming a value zero otherwise.

Usually, in IRT models it is assumed that there is one (dominant) latent variable that explains test performance. However, it may be clear *a priori* that multiple latent variables are involved or the dimensionality of the latent variable structure might not be clear at all. In these cases, **multidimensional**

IRT models can serve confirmatory and exploratory purposes. A multidimensional version of the GPCM is obtained by assuming a Q -dimensional latent variable $(\theta_{i1}, \dots, \theta_{iq}, \dots, \theta_{iQ})$ and by replacing $a_k\theta_i$ in (7) by

$$\sum_{q=1}^Q a_{kq}\theta_{iq}.$$

Usually, it is assumed that $(\theta_{i1}, \dots, \theta_{iq}, \dots, \theta_{iQ})$ has a multivariate normal distribution [16]. Since the model can be viewed as a factor-analysis model (see **Factor Analysis: Exploratory**) [23], the latent variables $(\theta_{i1}, \dots, \theta_{iq}, \dots, \theta_{iQ})$ are often called *factor-scores* while the parameters $(a_{k1}, \dots, a_{iq}, \dots, \theta_{iQ})$ are referred to as *factor-loadings*.

A General Framework for Assessing Model Fit

In this section, we will describe a general approach to assessing evaluation of fit to IRT models based on the Lagrange multiplier test [15, 1]. Let η_1 be a vector of the parameters of some IRT model, and let η_2 be a vector of parameters added to this IRT model to obtain a more general model. Let $\mathbf{h}(\eta_1)$ and $\mathbf{h}(\eta_2)$ be the first-order derivatives of the log-likelihood function. The parameters η_1 of the IRT model are estimated by maximum likelihood, so $\mathbf{h}(\eta_1) = \mathbf{0}$. The hypothesis $\eta_2 = \mathbf{0}$ can be tested using the statistic $LM = \mathbf{h}(\eta_2)^t \Sigma^{-1} \mathbf{h}(\eta_2)$, where Σ is the covariance matrix of $\mathbf{h}(\eta_2)$. Details on the computation of $\mathbf{h}(\eta_2)$ and Σ for IRT models in an MML framework can

be found in Glas [4, 5]. It can be proved that the LM-statistic has an asymptotic χ^2 -distribution with degrees of freedom equal to the number of parameters in η_2 . In the next sections, it will be shown how this can be applied to construct tests of fit to IRT models based on residuals.

Fit of the Response Functions

As above, the score range is partitioned into G subsets to form subgroups that are homogeneous with respect to θ . A problem with polytomously scored items is that there are often too few observations on low item categories in high number-correct score groups and in high item categories in low number-correct score groups. Therefore, we will consider the expectation of the item score, defined by

$$X_{ik} = \sum_{j=1}^{M_k} jY_{ikj}, \quad (8)$$

rather than the category scores themselves. In Figure 1, the expected item score function given θ for the GPCM is drawn as a dashed line.

To define the statistic, an indicator function $w(\mathbf{y}_i^{(k)}, g)$ is introduced that is equal to one if the number-correct score on the response pattern without item k , say $\mathbf{y}_i^{(k)}$, falls in subrange g , and equal to zero if this is not the case. We will now detail the approach further for the GPCM. The alternative model on which the LM test is based, is given by

$$\begin{aligned} P(Y_{ikj} = 1 | \theta_i, \delta_{kg}, w(\mathbf{y}_i^{(k)}, g) = 1) \\ = \frac{\exp(ja_k\theta_i + j\delta_g - b_{kj})}{1 + \sum_{h=1}^{M_k} \exp(ha_k\theta_i + h\delta_g - b_{kh})}, \end{aligned} \quad (9)$$

for $j = 1, \dots, M_k$. Under the null model, which is the GPCM model, the additional parameter δ_g is equal to zero. In the alternative model, δ_g acts as a shift in ability for subgroup g . If we define $\eta_2 = (\delta_1, \dots, \delta_g, \dots, \delta_G)$, the hypothesis $\eta_2 = \mathbf{0}$ can be tested using the LM-statistic defined above. It can be shown that $\mathbf{h}(\eta_2)$ is a vector of the differences between the observed and expected item scores in the subgroups $g = 1, \dots, G$. In an MML framework, the statistic is based on the differences

$$\sum_{i|g} x_{ik} - \sum_{i|g} E[X_{ik} | \mathbf{y}_i], \quad (10)$$

for $g = 1, \dots, G$, where the summations are over all respondents in subgroup g , and the expectation is the posterior expectation given response pattern $\mathbf{y}_i$ (for details, see [5]).

Evaluation of Local Independence

Also local independence can be evaluated using the framework of LM-tests. For the GPCM, dependency between the items k and item l can be modeled as

$$\begin{aligned} P(Y_{ikj} = 1, Y_{ilp} = 1 | \theta_i, \delta_{kl}) \\ = \frac{\exp(m\theta_i - b_{kj} + p\theta_i - b_{lp} + \delta_{kjl})}{1 + \sum_g \sum_h \exp(g\theta_i - b_{kg} + h\theta_i - b_{lh} + \delta_{kglh})}. \end{aligned} \quad (11)$$

Note the parameter δ_{kjl} models the association between the two items. The LM test can be used to test the special model, where $\delta_{kjl} = 0$, against the alternative model, where $\delta_{kjl} \neq 0$. In an MML framework, the statistic is based on the differences

$$n_{kjl} - E(N_{kjl} | \mathbf{y}_i), \quad (12)$$

where n_{kjl} is the observed number of respondents scoring in category j of item k and in category p of item l , and $E(N_{kl})$ is its posterior expectation (see, [5]). The statistic has an asymptotic χ^2 -distribution with $(M_k - 1)(M_l - 1)$ degrees of freedom.

Person-fit

The fact that person-fit statistics are computed using estimates of the proficiency parameters θ can lead to serious problems with respect to their distribution under the null-hypothesis [20]. However, person-fit statistics can also be redefined as LM-statistics. For instance, the UB-test can be viewed as a test whether the same proficiency parameter θ can account for the responses in all partial response patterns. For the GPCM, we model the alternative that this is not the case by

$$\begin{aligned} P(Y_{kj} = 1 | \theta, k \in A_g) \\ = \frac{\exp[m(\theta + \theta_g) - b_{kj}]}{1 + \sum_{h=1}^{M_k} \exp[h(\theta + \theta_g) - b_{kh}]}. \end{aligned} \quad (13)$$

One subtest, say the first, should be used as a reference. Further, the test length is too short to consider too many subtests, so usually, we only consider two subtests. Defining $\eta_2 = \theta_2$ leads to a test statistic for assessing whether the total score on the second part of the test is as expected from the first part of the test.

An Example

Part of a school effectiveness study serves as a very small illustration. In a study of the effectiveness of Belgium secondary schools, several cognitive and noncognitive tests were administered to 2207 pupils at the end of the first, second, fourth, and sixth school year. The ultimate goal of the analyses was to estimate a correlation matrix between all scales over all time points using concurrent MML estimates of a multidimensional IRT model. Here we focus on the first step of these analyses, which was checking whether a one-dimensional GPCM held for each scale at each time point. The example pertains to the scale for ‘Academic Self Esteem’ which consisted of 9 items with five response categories each. The item parameters were estimated by MML assuming a standard normal distribution for θ . To compute the LM-statistics, the score range was divided into four sections in such a way that the numbers of respondents scoring in the sections were approximately equal. Section 1 contained the (partial) total-scores $r \leq 7$, Section 2 contained the scores $8 \leq r \leq 10$, Section 3 the scores $11 \leq r \leq 13$, and Section 4 $r \geq 14$. The results are given in Table 1. The column labeled ‘LM’ gives the values of the LM-statistics; the column labeled ‘Prob’ gives the significance probabilities. The statistics have three degrees of freedom.

Note that 6 of the 9 LM-tests were significant at a 5% significance level. To assess the seriousness of the misfit, the observed and the expected average item scores in the subgroups are shown under the headings ‘Obs’ and ‘Exp’, respectively. Note that the observed average scores increased with the score level of the group. Further, it can be seen that the observed and expected values were quite close: the largest absolute difference was .09 and the mean absolute difference was approximately .02. So from the values of the LM-statistics, it must be concluded that the observed item scores are definitely outside the confidence intervals of their expectations, but the precision of the predictions from the model is good enough to accept the model from the intended application.

Conclusion

The principles sketched above pertain to a broad class of parameterized IRT models, both in a logistic or normal-ogive formulation, and their multidimensional generalizations. The focus was on a likelihood-based framework. Recently, however, a Bayesian estimation framework for IRT models has emerged [14, 3] (see **Bayesian Item Response Theory Estimation**). Evaluation of model fit can be based on the same rationales and statistics as outlined above, only here test statistics are implemented as so-called posterior predictive check. Examples of this approach are given by Hoijsink [8] and Glas and Meijer [6], who show how item- and person-fit statistics can be used as posterior predictive checks.

Another important realm of IRT are the so-called nonparametric IRT models [17, 21]. Also here

Table 1 Results of the LM test to evaluate fit of the item response functions for the scale ‘academic self esteem’

Item	LM	Prob	Group 1		Group 2		Group 3		Group 4	
			Obs	Exp	Obs	Exp	Obs	Exp	Obs	Exp
1	7.95	0.05	1.37	1.37	1.68	1.71	1.90	1.87	2.10	2.07
2	11.87	0.01	0.45	0.50	0.85	0.87	1.23	1.16	1.61	1.64
3	9.51	0.02	0.70	0.77	1.21	1.19	1.53	1.49	1.91	1.92
4	0.64	0.89	0.98	0.97	1.36	1.36	1.60	1.62	1.99	1.98
5	10.62	0.01	0.32	0.33	0.73	0.71	0.99	0.98	1.31	1.34
6	16.90	0.00	0.34	0.33	0.67	0.67	0.98	0.94	1.26	1.31
7	15.17	0.00	0.77	0.77	1.19	1.19	1.48	1.45	1.78	1.85
8	2.37	0.50	0.73	0.72	1.12	1.10	1.35	1.36	1.76	1.77
9	2.41	0.49	1.56	1.54	1.81	1.85	2.04	2.01	2.21	2.23

fit to IRT models can be evaluated by comparing observed proportions and expected probabilities of item responses conditional on number-correct scores, response probabilities in subpopulations, and responses to pairs of items. So the principles are the same as in parametric IRT models, but the implementation differs between applications.

Model Identifiability

In some statistical models, different parameter values can give rise to identical probability distributions. When this happens, there will be a number of different parameter values associated with the **maximum likelihood** of any set of observed data. This is referred to as the model identifiability problem. For example, suppose someone attempts to compute the regression equation predicting Y from three variables X_1 , X_2 , and their sum $(X_1 + X_2)$, the program will probably crash or give an error message because it cannot find a unique solution. The model is the same if $Y = 0.5X_1 + 1.0X_2 + 1.5(X_1 + X_2)$, $Y = 1.0X_1 + 1.5X_2 + 1.0(X_1 + X_2)$, or $Y = 2.0X_1 + 2.5X_2 + 0.0(X_1 + X_2)$; indeed there are an infinite number of equally good possible solutions. Model identifiability is a particular problem for the latent class model, a statistical method for finding the underlying traits from a set of psychological tests, because, by postulating latent variables, it is easy to introduce more parameters into a model than can be fitted from the data.

A model is identifiable if the parameter values uniquely determine the probability distribution of the data and the probability distribution of the data uniquely determines the parameter values. Formally, let ϕ be the parameter value of the model, y be the observed data, and $F(y; \phi)$ be the probability distribution of the data. A model is identifiable if for all $(\phi_0, \phi) \in \Phi$ and for all $y \in S_Y$:

$$F(y; \phi_0) = F(y; \phi) \text{ if and only if } \phi_0 = \phi, \quad (1)$$

where Φ denotes the set of all possible parameter values, and S_Y is the set of all possible values of the data.

The most common cause of model nonidentifiability is a poorly specified model. If the number of unique model parameters exceeds the number of independent pieces of observed information, the model is not identifiable. Consider the example of a latent class model that classifies people into three states (severely depressed/mildly depressed/not depressed) and that is used to account for the responses of a group of people to three psychological tests with binary (positive/negative) outcomes. Let (Y_1, Y_2, Y_3) denote the test results and let each take the value

1 when the outcome is positive and 0 when it is negative. S specifies the unobservable states where $S = 1$ where there is no depression, 2 where the depression is mild, and 3 where the depression is severe. The probability of the test results is then

$$\begin{aligned} & \Pr(Y_1 = y_1, Y_2 = y_2, Y_3 = y_3) \\ &= \sum_{j=1}^3 \Pr(S = j) \prod_{m=1}^3 \Pr(Y_m = 1|S = j)^{y_m} \\ & \quad \times \Pr(Y_m = 0|S = j)^{1-y_m}. \end{aligned} \quad (2)$$

The test results have $2^3 - 1 = 7$ independent patterns and the model requires 11 unique parameters (Two probabilities for depression status $\Pr(S = 3)$, $\Pr(S = 2)$, and one conditional probability $\Pr(Y_m = 1|S = j)$ for each depression status j and test m); therefore, the model is not identifiable.

If the model is not identifiable, one can make it so by imposing various constraints upon the parameters. When there appears to be sufficient total observed information for the number of estimated parameters, it is also necessary to specify the model unambiguously. For the above latent class model, suppose that, for the second and third tests, the probabilities of observing a positive test result are the same for people with severe, mild, or no depression (i.e., $\Pr(Y_m = 1|S = 3) = \Pr(Y_m = 1|S = 2) = \Pr(Y_m = 1|S = 1) = p_m$ for $m = 2, 3$). In other words, only the first test discriminates between the unobservable states of depression. The model now has only seven parameters, which is equal to the number of independent test result patterns. The probability distribution of test results becomes

$$\begin{aligned} & \Pr(Y_1 = y_1, Y_2 = y_2, Y_3 = y_3) \\ &= \Theta \prod_{m=2}^3 (p_m)^{y_m} (1 - p_m)^{1-y_m}, \end{aligned} \quad (3)$$

where

$$\begin{aligned} \Theta &= (1 - \eta_2 - \eta_3)(p_{11})^{y_1}(1 - p_{11})^{1-y_1} \\ & \quad + \eta_2(p_{12})^{y_1}(1 - p_{12})^{1-y_1} \\ & \quad + \eta_3(p_{13})^{y_1}(1 - p_{13})^{1-y_1}, \end{aligned} \quad (4)$$

$\eta_2 = \Pr(S = 2)$, $\eta_3 = \Pr(S = 3)$, $p_{11} = \Pr(Y_1 = 1|S = 1)$, $p_{12} = \Pr(Y_1 = 1|S = 2)$, and $p_{13} = \Pr(Y_1 = 1|S = 3)$. Θ imposes two restrictions on parameters

(i.e., for $y_1 = 1$ or 0), and there are five parameters to consider (i.e., η_2 , η_3 , p_{11} , p_{12} and p_{13}). Because the number of restrictions is less than the number of parameters of interest, Θ and the above latent class model are not identifiable – the same probability distributions could be generated by supposing that there was a large chance of being in a state with a small effect on the probability of being positive on test 1 or by supposing that there was a small chance of being in this state but it was associated with a large probability of responding positively.

Sometimes it is difficult to find an identifiable model. A weaker form of identification, called *local identifiability*, may exist, namely, it may be that other parameters generate the same probability distribution as ϕ_0 does, but one can find an open neighborhood of ϕ_0 that contains none of these parameters [3]. For example, we are interested in β in the regression $Y = \beta^2 X$ (the square root of the association between Y and X). $\beta = 1$ and $\beta = -1$ result in the same Y prediction; thus, the model is not (globally) identifiable. However, the model is locally identifiable because one can easily find two nonoverlapping intervals $(0.5, 1.5)$ and $(-1.5, -0.5)$ for 1 and -1 , respectively. A locally but not globally identifiable model does not have a unique interpretation, but one can be sure that, in the neighborhood of the selected solution, there exist no other equally good solutions; thus, the problem is reduced to determining the regions where local identifiability applies. This concept is especially useful in models containing nonlinearities as the above regression example, or models with complex structures, for example, **factor analysis**, latent class models and **Markov Chain Monte Carlo**.

It is difficult to specify general conditions that are sufficient to guarantee (global) identifiability. Fortunately, it is fairly easy to determine local identifiability. One can require that the columns of the Jacobian matrix, the first-order partial derivative of the

likelihood function with respect to the unique model parameters, are independent [2, 3]. Alternatively, we can examine whether the Fisher information matrix possesses **eigenvalues** greater than zero [4]. Formann [1] showed that these two approaches are equivalent. A standard practice for checking local identifiability involves using multiple sets of initial values for parameter estimation. Different sets of initial values that yield the same likelihood maximum should result in the same final parameter estimates. If not, the model is not locally identifiable.

When applying a nonidentifiable model, different people may draw different conclusions from the same model of the observed data. Before one can meaningfully discuss the estimation of a model, model identifiability must be verified. If researchers come up against identifiability problems, they can first identify the parameters involved in the lack of identifiability from their extremely large asymptotic standard errors [1], and then impose reasonable constraints on identified parameters based on prior knowledge or empirical information.

Model Selection

When a behavioral scientist statistically models relationships among a set of variables, the goal is to provide a meaningful and parsimonious explanation for those relationships, ultimately achieving a close approximation to reality. However, given the complexity inherent in social science data and the phenomena they attempt to capture, there are typically multiple plausible explanations for any given set of observations. Even when one model fits well, other models with different substantive interpretations are virtually always possible. The task at hand, then, is to determine ‘which models are the “fittest” to survive’ [1, p. 71]. In this article, I will review issues to consider when selecting among alternative models, using **structural equation modeling** (SEM) as a context. However, the same general principles apply to other types of statistical models (e.g., **multiple regression**, **analysis of variance**) as well.

In light of the existence of multiple viable explanations for a set of relationships, one approach is to formulate multiple models in advance, test each with the same set of data, and determine which model shows superior qualities in terms of fit, parsimony, interpretability, and meaningfulness. Each model should have a strong theoretical rationale. Justifications for such a *model comparison* strategy are many. For example, this approach is quite reasonable when investigating a new research domain – if a phenomenon is not yet well understood, there is typically some degree of uncertainty about how it operates, so it makes sense to explore different alternatives [4]. This exploration should happen at the model-development stage (*a priori*) rather than at the model-fitting stage (*post hoc*), to avoid capitalizing on chance. Even in established lines of research, scientists may have competing theoretical propositions to test, or equivocal findings from prior research could suggest multiple modeling possibilities. Finally, researchers can argue more persuasively for a chosen model if they can demonstrate its statistical superiority over rival, theoretically compelling models. For this reason, some methodologists advocate that consideration of multiple alternatives be standard practice when modeling behavioral phenomena [e.g., [2, 5]].

After one has found strong, theoretically sensible results for a set of competing models, the question of

selection then arises: Which model to retain? **Model selection** guidelines vary depending on whether the alternative models are nested or nonnested. Generally speaking, if Model B is *nested* within Model A, then Model B contains the same variables as Model A but specifies fewer relations among them. In other words, Model B is a special case or a subset of Model A; because it is more restrictive, Model B cannot fit the data as well [6]. However, Model B provides a more parsimonious explanation of the data, so if the decrement in overall fit is trivial, then B is often considered the better model.

To compare the fit of nested structural equation models, the *chi-square difference test* (also termed the Likelihood Ratio or LR test – see **Maximum Likelihood Estimation**) is most often employed. For example, when comparing nested Models A and B, the researcher estimates both models, computing the overall χ^2 fit statistic for each. She or he then calculates the difference between the two χ^2 values ($\chi^2_{\text{ModelA}} - \chi^2_{\text{ModelB}}$). The result is distributed as a χ^2 , with degrees of freedom (df) equal to the difference in df for the two models ($\text{df}_{\text{ModelA}} - \text{df}_{\text{ModelB}}$). If this value is significant (according to a chi-square table), then the restrictions imposed in the smaller Model B led to a significant worsening of fit, so the more comprehensive Model A should be retained. (Another way to characterize this same situation is to say that the additional relationships introduced in Model A led to a significant improvement in fit – again suggesting that Model A should be retained.) However, if this test does not point to a significant difference in the fit of these two models, the simpler, nested Model B is typically retained [e.g., 1, 6].

When comparing alternative models that are *nonnested*, a chi-square difference test is not appropriate. Instead, one can rely on ‘information measures of fit’, such as **Akaike’s Information Criterion** (AIC), the *Corrected Akaike’s Information Criterion* (CAIC), or the single-sample *Expected Cross Validation Index* (ECVI). These measures do not appear often in behavioral research, but they are appropriate for the comparison of alternative nonnested models. The researcher simply estimates the models, computes one of these fit indices for each, and then rank-orders the models according to the chosen index; the model with the lowest index value shows the best fit to the data [3].

In the cases reviewed above, only overall ‘goodness of fit’ is addressed. However, during model

2 Model Selection

selection, researchers should also pay close attention to the substantive implications of obtained results: Are the structure, valence, and magnitude of estimated relationships consistent with theory? Are the parameter estimates interpretable and meaningful? Even if fit indices suggest one model to be superior to others, this model is useless if it makes no sense from a substantive perspective [4]. Moreover, there often exist multiple plausible models that are mathematically comparable and yield identical fit to a given dataset. These *equivalent models* differ only in terms of substantive meaning, so this becomes the primary factor driving model selection [5].

One final *caveat* about model selection bears mention. Even after following all of the practices reviewed here – specifying a parsimonious model based on strong theory, testing it against viable alternatives, and evaluating it to have superior fit and interpretability, a researcher still cannot definitively claim to have captured ‘Truth,’ or even to have identified THE model that BEST approximates reality. Many, many models are always plausible, and selection of an excellent model could artifactually result from failure to consider every possible alternative [4, 5]. With behavioral processes being the complex, messy phenomena that they are, we can only aspire to represent them *imperfectly* in statistical models,

rarely (if ever) knowing the ‘true’ model. Ay, there’s the rub [6].

Models for Matched Pairs

When **randomization** is impractical or impossible, matched studies are often used to enhance the comparability of comparison groups, so as to facilitate the assessment of the association between an exposure and an event while minimizing confounding. Matched pairs designs, which tend to be more resistant to biases than are **historically controlled studies**, are characterized by a particular type of statistical dependence, in which each pair in the sample contains observations either from the same subject or from subjects that are related in some way (*see Matching*). The matching is generally based on subject characteristics such as age, gender, or residential zip code, but could also be on a propensity score based on many such subject characteristics [13]. The standard design for such studies is the **case-control study**, in which each case is matched to either one control or multiple controls. The simplest example would probably be binary data (*see Binomial Distribution: Estimating and Testing Parameters*) with one-to-one matched pairs, meaning that the response or outcome variable is binary and each case is matched to a single control.

There are several approaches to the analysis of matched data. For example, the matched pairs t Test can be used for a continuous response. Stratified analysis, the McNemar test [11], and conditional logistic regression [6, 7] can be used for data with discrete or binary responses. In some cases, it even pays to break the matching [9].

The Matched Pairs t Test

The matched pairs t Test is used to test for a difference between measurements taken on subjects before an intervention or an event versus measurements taken on them after an intervention or an event. In the test, each subject is allowed to serve as his or her own control. The matched paired t Test reduces confounding that could result from comparing one group of subjects receiving one treatment to a different group of subjects receiving a different treatment.

Let $X = (x_1, x_2, \dots, x_n)$ be the first observations from each of the n subjects, and let $Y = (y_1, y_2, \dots, y_n)$ be the second observations from the

same n subjects. The test statistic is a function of the differences $d = (d_1, d_2, \dots, d_n)$, where $d_i = x_i - y_i$. If the d_i can be considered to have a normal distribution (an assumption not to be taken lightly [2, 4]) with mean zero and arbitrary variance, then it is appropriate to use the t Test. The test statistic can be written as follows:

$$t = \frac{\sum_i d_i / n}{\left(\frac{S_d}{\sqrt{n}} \right)}, \quad (1)$$

where S_d is the standard deviation computed from $(d_1, d_2, \dots, d_n)$. t follows a Student's t distribution (*see Catalogue of Probability Density Functions*)(with mean zero) under the null hypothesis. If this test is rejected, then one would conclude that the before and after observations from the same pair are not equivalent to each other.

The McNemar Test

When dealing with discrete data, we denote by π_{ij} the probability of the first observation of a pair having outcome i and the second observation having outcome j . Let n_{ij} be the number of such pairs. Clearly, then, π_{ij} can be estimated by n_{ij}/n , where n is the total number of pairs in the data. If the response is binary, then McNemar's test can be applied to test the marginal homogeneity of the **contingency table** with an exposure and an event. That is, McNemar's test tests the null hypothesis that $H_0: \pi_{+1} = \pi_{1+}$, where $\pi_{+1} = \pi_{11} + \pi_{21}$ and $\pi_{1+} = \pi_{11} + \pi_{12}$. This is equivalent, of course, to testing the null hypothesis that $\pi_{21} = \pi_{12}$. This is called *symmetry*, as in Table 1. The McNemar test statistic z_0 is computed as follows:

$$z_0 = \frac{n_{21} - n_{12}}{(n_{21} + n_{12})^{1/2}}. \quad (2)$$

Table 1 The Structure of a Hypothetical 2×2 Contingency Table

	Before		Total
	1	2	
After			
1	π_{11}	π_{12}	π_{1+}
2	π_{21}	π_{22}	π_{2+}
Total	π_{+1}	π_{+2}	π_{++}

2 Models for Matched Pairs

Now asymptotically z_0^2 follows a χ^2 distribution with degree of freedom equal to 1. One can also use a continuity correction, an exact test, or still other variations [10].

Stratified Analysis

Stratified analysis is used to control confounding by covariates that are associated with both the outcome and the exposure [14]. For example, if a study examines the association between smoking and lung cancer among several age groups, then age may have a confounding effect on the apparent association between smoking and lung cancer, because there may be an age imbalance with respect to both smoking and incidence of lung cancer. In such a case, the data would need to be stratified by age (*see Stratification*). One method for doing this is the **Mantel-Haenszel test** [10], which is performed to measure the average conditional association by estimating the common **odds ratio** as the sum of weighted odds ratios from each stratum. Of course, in reality, the odds ratios across the strata need not be common, and so the **Breslow-Day test** [5] can be used to test the homogeneity of odds ratios across the strata. If the strata do not have a common odds ratio, then the association between smoking and lung cancer should be tested separately in each stratum.

Conditional Logistic Regression

If the matching is one-to-one so that there is one control per case, and if the response is binary with outcomes 0 and 1, then within each matched set there are four possibilities for the pair (case, control): (1,0), (0,1), (1,1), (0,0). Denote by (Y_{i1}, Y_{i2}) the two observations of the i th matched set. Then the conditional **logistic regression** model can be expressed as follows:

$$\begin{aligned} \text{logit}[P(Y_{it} = 1)] &= \alpha_i + \beta x_{it} \\ i &= 1, 2, \dots, n; \quad t = 1, 2, \end{aligned} \quad (3)$$

where x_{it} is the explanatory variable of interest and α_i and β are model parameters. In particular, α_i describes the matched-set-specific effect while β is a common effect across pairs. With the above

model, one can assume independence of the observations, both for different subjects and within the same subject.

Hosmer and Lemeshow [8] provide a dataset with 189 observations representing 189 women, of whom 59 had low birth-weight babies and 130 had normal-weight babies. Several risk factors for low birth-weight babies were under investigation. For example, whether the mother smoked or not (sm) and history of hypertension (ht) were considered as possible predictors, among others. A subset containing data from 20 women is used here (Table 2) as an example to illustrate the 1:1 matching. Specifically, 20 women were matched by age (to the nearest year), and divided accordingly into 10 strata. In each age stratum, there is one case of low birth weight ($bwt = 1$) and one control ($bwt = 0$).

The conditional logistic regression model for this data set can be written as follows:

$$\begin{aligned} \text{logit}[P(Y_{it} = 1)] &= \alpha_i + \beta_{\text{sm}} x_{\text{sm},it}, \\ i &= 1, 2, \dots, 10, \quad t = 1, 2, \end{aligned} \quad (4)$$

where Y_{it} represents the outcome for woman t in age group i , α_i is the specific effect in age group i ,

Table 2 An example of a matched data set. A data extracted from Hosmer, D.W. & Lemeshow, S. (2000). *Applied Logistic Regression*, 2nd Edition, Wiley-Interscience

Stratum	<i>bwt</i>	Age	Race	Smoke	ht
1	0	14	1	0	0
1	1	14	3	1	0
2	0	15	2	0	0
2	1	15	3	0	0
3	0	16	3	0	0
3	1	16	3	0	0
4	0	17	3	0	0
4	1	17	3	1	0
5	0	17	1	1	0
5	1	17	1	1	0
6	0	17	2	0	0
6	1	17	1	1	0
7	0	17	2	0	0
7	1	17	2	0	0
8	0	17	3	0	0
8	1	17	2	0	1
9	0	18	1	1	0
9	1	18	3	0	0
10	0	18	1	1	0
10	1	18	2	1	0

and $x_{sm,it}$ represents the smoking status of woman t in age group i , which can be either 1 or 0. In this particular case, β_{sm} is estimated to be 0.55. Therefore, the odds of having low birth-weight babies for woman in group i who smoke is $\exp(\beta_{sm}) = 1.74$ times the odds for woman in the same group who don't smoke.

Conditional logistic regression can also be used in $n:m$ matching scenario. If the complete low birth-weight dataset from Hosmer and Lemeshow [8] is used, then each age stratum, instead of having one case and one control, contains multiple cases and multiple controls. Similar conditional logistic regression model can be applied.

The conditional logistic regression model can also include extra predictors for the covariates that are not controlled by matched pairs. It is also possible to treat the α_i 's as random effects to eliminate the large number of nuisance parameters. The pair-specific effect can be modeled as a parameter following some normal distribution with unknown mean and variance. If, instead of the two levels that would prevail in the binary response case, the response has $J > 2$ levels, then a reference level is chosen for the purpose of comparisons. Without loss of generality, say that level J is considered to be the reference level, to which other levels are compared. Then the model is as follows:

$$\log \left(\frac{P(Y_{it} = k)}{P(Y_{it} = J)} \right) = \alpha_{ik} + \beta_k x_{it},$$

$$k = 1, 2, \dots, J - 1, t = 1, 2. \quad (5)$$

Clearly, this is a generalization of the model for binary data. Specialized methods also exist for analyzing matched pairs in a nonparametric fashion with missing data without assuming that the missing data are missing completely at random (see **Missing Data**) [1]. When considering 2×2 matched pairs and testing for noninferiority, it has been found that asymptotic tests may exceed the claimed nominal Type I error rate [12], and so an exact test (see **Exact Methods for Categorical Data**) would generally be preferred. The very term 'exact test' may appear to be a misnomer in the context of a matched design, because there is neither random sampling nor random allocation, and hence, technically, no basis for formal hypothesis testing [3]. However, the basis for inference in matched designs is distinct from that of randomized designs, which

involve either random sampling or random allocation (see **Randomization Based Tests**). Specifically, while in a randomized design the outcome of a given subject exposed at a given time to a given treatment is generally taken as fixed (not random), the outcome of a matched design is taken as the random quantity. So here the randomness is a within-subject factor, or, more correctly, is random even within the combination of subject, treatment, and time. That such a random component to the outcomes exists needs to be determined on a case-by-case basis. Rubin [13] pointed out that the lack of randomization creates sensitivity to the assignment mechanism, which cannot be avoided simply by using Bayesian methods instead of randomization-based methods.

Moderation

Every field of scientific inquiry begins with the search for universal predictor–criterion correlations. Unfortunately, universal relationships rarely exist in nature [4]. At best, researchers find that their hypothesized correlations are weaker than expected. At worst, the hypothesized correlations are wildly inconsistent from study to study. The resulting cacophony has caused more than a few researchers to abandon promising lines of research for others that are (hopefully) more tractable.

In some cases, however, these counterintuitive or conflicting findings motivate the researchers to reexamine their underlying theoretical models. For example, the researchers may attempt to specify the conditions under which the hypothesized predictor–criterion relationship will hold true. This theoretical-based search for moderator variables – or interaction effects – is one indication of the sophistication or maturity of a field of study [3].

The Moderator-mediator Distinction

Many researchers confuse the concepts of moderation and **mediation** [3, 5]. However, the distinction is relatively simple. Moderation concerns the effect of a third variable (z) on the strength or direction of a predictor–criterion ($x - y$) correlation. Therefore, moderation addresses the issues of ‘when?’, ‘for whom?’, or ‘under what conditions?’ does the hypothesized predictor–criterion correlation hold true. In essence, moderator variables are nothing more than **interaction effects**.

A moderated relationship is represented by a single, nonadditive, linear function where the criterion variable (y) varies as a product of the independent (x) and moderator variables (z) [5]. Algebraically, this function is expressed as $y = f(x, z)$. When analyzed using multiple regression, the function is usually expressed as $y = b_1x + b_2z + b_3xz + e$. Specifically, the predicted value of y is modeled as a function of the independent variable (x), the moderator variable (z), their interaction (xz), and measurement error (e). Graphically, mediated relationships are represented by an arrow from the moderator (z) that intersects the $x - y$ relationship at a 90° angle (see Figure 1). Although

Figure 1 Examples of (a) direct, (b) moderated, and (c) mediated relationships

moderated relationships can help resolve apparently contradictory research findings, they do not imply causality.

By contrast, mediation represents one or more links in the causal chain (z) between the predictor (x) and criterion (y) variables. Therefore, mediation addresses the issues of ‘how?’ or ‘why?’ the predictor variable influences the criterion [3]. In essence, mediator variables are caused by the predictor and, in turn, predict the criterion.

Unlike moderated relationships, mediated relationships are represented by two or more additive, linear functions. Algebraically, these functions are expressed as $y = f(x)$, $z = f(x)$, and $y = f(z)$. When analyzed using **multiple regression**, these functions are usually expressed as $z = bx + e$ and $y = bz + e$. Specifically, the predicted value of the mediator (z) varies as a function of the independent variable (x) and measurement error (e). In addition, the predicted value of the criterion variable (y) varies as a function of the mediator (z) and measurement error (e). Graphically, moderated relationships are represented as a series of arrows in which the predictor variable influences the mediator variable, which in turn influences the criterion variable (see Figure 1). Unlike moderated relationships, mediated relationships specify the chain of causality [3, 5].

Testing Moderated Relationships

Moderated relationships can be tested in a variety of ways. When both the predictor and moderator variables are measured as categorical variables, the moderated relationship can be tested using **analysis of variance** (ANOVA). However, when one or both are measured on a continuous scale, hierarchical regression is preferred (*see Hierarchical Models*). Many researchers favor regression because it is more flexible than ANOVA. It also eliminates the need to artificially dichotomize continuous variables. Regardless of which analytical technique is used, the tests are conducted in very similar ways.

First, the researcher needs to carefully choose the moderator variable. The moderator variable is typically selected on the basis of previous research, theory, or both. Second, the researcher needs to specify the nature of the moderated relationship. Most common are enhancing interactions, which occur when the moderator enhances the effect of the predictor variable, or buffering interactions, which occur when moderator weakens the effect of the predictor variable. Less common are antagonistic interactions, which occur when the predictor and moderator variables have the same effect on the criterion, but their interaction produces an opposite effect [3].

Third, the researcher needs to ensure that the study has sufficient statistical **power** to detect an interaction effect. Previous research suggests that the power to detect interactions is substantially lower than the 0.80 threshold [1]. Researchers should consider several factors when attempting to maximize their study's statistical power. For example, researchers should consider not only the total effect size (R^2) but also the incremental effect size (ΔR^2) when selecting the necessary minimum sample sizes. Other important tasks include selecting reliable and valid measures, taking steps such as oversampling to avoid range restriction, centering predictor variables to reduce collinearity, and ensuring that subgroups have equivalent sample sizes and error variances (i.e., when one or more of the variables is measured on a categorical scale) [3].

Fourth, the researcher needs to create the appropriate product terms. These product terms, which are created by multiplying the predictor and moderator variables, represent the interaction between them.

Fifth, the researcher needs to structure the equation. For example, using hierarchical regression, the researcher would enter the predictor and moderator variables during the first step. After controlling for these variables, the researcher would enter the interaction terms during the second step. The significance of the interaction term is determined by examining the direction of the interaction term's regression weight, the magnitude of the effect (ΔR^2), and its statistical significance [3].

Finally, the researcher should plot the effects to determine the type of effect. For each grouping variable, the researcher should plot the scores at the mean, one standard deviation above the mean, and one standard deviation below the mean. These plots should help the researcher to visualize the form of the moderator effect: an enhancing interaction, a buffering interaction, or an antagonistic interaction. Alternatively, the researcher could test the statistical significance of the simple regression slopes for different values of the moderator variable [2].

Miscellaneous

In this entry, we explored the basics of moderation, the search for interaction effects. The discussion was limited to single-sample studies using analytical techniques such as ANOVA or hierarchical regression. However, moderator analyses can also be assessed in other ways. For example, moderators can be assessed in **structural equation modeling** (SEM) or **meta-analysis** by running the model separately for various subgroups and comparing the two sets of results.

Regardless of how moderators are tested, previous research suggests that tests for moderation tend to be woefully underpowered. Therefore, it should come as no surprise that many researchers have failed to find significant interaction effects, even though they are believed to be the norm, rather than the exception [4].

Moments

Moments are an important class of **expectation** used to describe probability distributions. Together, the entire set of moments of a random variable will generally determine its probability distribution exactly.

There are three main types of moments:

1. raw moments,
2. central moments, and
3. factorial moments.

Raw Moments

Where a random variable is denoted by the letter X , and k is any positive integer, the k th raw moment of X is defined as $E(X^k)$, the expectation of the random variable X raised to the power k . Raw moments are usually denoted by μ'_k where $\mu'_k = E(X^k)$, if that expectation exists. The first raw moment of X is $\mu'_1 = E(X)$, also referred to as the mean of X . The second raw moment of X is $\mu'_2 = E(X^2)$, the third $\mu'_3 = E(X^3)$, and so on. If the k th moment of X exists, then all moments of lower order also exist. Therefore, if the $E(X^2)$ exists, it follows that $E(X)$ exists.

Central Moments

Where X again denotes a random variable and k is any positive integer, the k th central moment of X is defined as $E[(X - c)^k]$, the expectation of X minus a constant, all raised to the power k . Where the constant is the mean of the random variable, this is referred to as the k th central moment around the mean. Central moments around the mean are usually denoted by μ_k where $\mu_k = E[(X - \mu_X)^k]$. The first central moment is equal to zero as $\mu_1 = E[(X - \mu_X)] = E(X) - E(\mu_X) = \mu_X - \mu_X = 0$. In fact, if the probability distribution is symmetrical around the mean (e.g., the normal distribution) all odd central moments of X around the mean are equal to zero, provided they exist. The most important central moment is the second central moment of X around the mean. This is $\mu_2 = E[(X - \mu_X)^2]$, the variance of X .

The third central moment about the mean, $\mu_3 = E[(X - \mu_X)^3]$, is sometimes used as a measure of

Figure 1 An example of an asymmetrical probability distribution where the third central moment around the mean is equal to zero

asymmetry or **skewness**. As an odd central moment around the mean, μ_3 is equal to zero if the probability distribution is symmetrical. If the distribution is negatively skewed, the third central moment about the mean is negative, and if it is positively skewed, the third central moment around the mean is positive. Thus, knowledge of the shape of the distribution provides information about the value of μ_3 . Knowledge of μ_3 does not necessarily provide information about the shape of the distribution, however. A value of zero may not indicate that the distribution is symmetrical. As an illustration of this, μ_3 is approximately equal to zero for the distribution depicted in Figure 1, but it is not symmetrical. The third central moment is therefore not used much in practice.

The fourth central moment about the mean, $\mu_4 = E[(X - \mu_X)^4]$, is sometimes used as a measure of excess or **kurtosis**. This is the degree of flatness of the distribution near its center. The coefficient of kurtosis $(\mu_4/\sigma^4 - 3)$ is sometimes used to compare an observed distribution to that of a normal curve. Positive values are thought to be indicative of a distribution that is more peaked around its center than that of a normal curve, and negative values are thought to be indicative of a distribution that is more flat around its center than that of a normal curve. However, as was the case for the third central moment around the mean, the coefficient of kurtosis does not always indicate what it is supposed to.

Factorial Moments

Finally, where X denotes a random variable and k is any positive integer, the k th factorial moment of X is defined as the following expectation $E[X(X-1)\dots(X-k+1)]$. The first factorial moment of X is therefore $E(X)$, the second factorial moment of X is $E[(X-1+1)(X-2+1)] = E(X^2 - X)$, and so on. Factorial moments are easier to calculate than raw moments for some random variables (usually discrete). As raw moments can be obtained from factorial moments and vice versa, it is sometimes easier to obtain the raw moments for a random variable from its factorial moments.

Moment Generating Function

For each type of moment, there is a function that can be used to generate all of the moments of a random variable or probability distribution. This is referred to as the 'moment generating function' and denoted by mgf, $m_X(t)$ or $m(t)$. In practice, however, it is often easier to calculate moments directly. The main use of the moment generating function is therefore in

characterizing a distribution and for theoretical purposes. For instance, if a moment generating function of a random variable exists, then this moment generating function uniquely determines the corresponding distribution function. As such, it can be shown that if the moment generating functions of two random variables both exist and are equal for all values of t in an interval around zero, then the two cumulative distribution functions are equal. However, existence of all moments is not equivalent to existence of the moment generating function.

More information on the topic of moments and moment generating functions is given in [1, 2, 3].

Monotonic Regression

In linear regression, we fit a linear function $y = \alpha + \beta x$ to a scatterplot of n points (x_i, y_i) . We find the parameters α and β by minimizing

$$\sigma(\alpha, \beta) = \sum_{i=1}^n w_i (y_i - \alpha - \beta x_i)^2, \quad (1)$$

where the w_i are known positive weights (*see Multiple Linear Regression*).

In the more general **nonlinear regression** problem, we fit a nonlinear function $\phi_\theta(x)$ by minimizing

$$\sigma(\theta) = \sum_{i=1}^n w_i (y_i - \phi_\theta(x_i))^2 \quad (2)$$

over the parameters θ . In both cases, consequently, we select the minimizing function from a family of functions indexed by a small number of parameters.

In some statistical techniques, low-dimensional parametric models are too restrictive. In nonmetric **multidimensional scaling** [3], for example, we can only use the rank order of the x_i and not their actual numerical values. Parametric methods become useless, but we still can fit the best fitting monotone (increasing) function nonparametrically. Suppose there are no ties in x , and the x_i are ordered such that $x_1 < \dots < x_n$. In monotone regression, we minimize

$$\sigma(z) = \sum_{i=1}^n w_i (y_i - z_i)^2 \quad (3)$$

over z , under the linear inequality restrictions that $z_1 \leq \dots \leq z_n$. If the solution to this problem is $\hat{z}$, then the best fitting increasing function is the set of pairs $(x_i, \hat{z}_i)$. In monotone regression, the number of parameters is equal to the number of observations. The only reason we do not get a perfect solution all the time is because of the order restrictions on z .

Actual computation of the best fitting monotone function is based on the theorem that if $y_i > y_{i+1}$, then $\hat{z}_i = \hat{z}_{i+1}$. In words: if two consecutive values of y are in the wrong order, then the two corresponding consecutive values of the solution $\hat{z}$ will be equal. This basic theorem leads to a simple algorithm, because knowing that two values of $\hat{z}$ must be equal reduces the number of parameters by one. We thus have a monotone regression problem with $n - 1$

parameters. Either the elements are now in the correct order, or there is a violation, in which case we can reduce the problem to one with $n - 2$ parameters, and so on. This process always comes to an end, in the worst possible case when we only have a single parameter left, which is obviously monotone.

We can formalize this in more detail as the up-and-down-blocks algorithm of [4]. It is illustrated in Table 1, in which the first column is y . The first violation we find is $3 > 0$, or 3 is not up-satisfied. We merge the two elements to a block, which contains their weighted average $3/2$ (in our example all weights are one). But now $2 > (3/2)$, and thus the new value $3/2$ is not down-satisfied. We merge all three values to a block of three and find $5/3$, which is both up-satisfied and down-satisfied. We then continue with the next violation. Clearly, the algorithm produces a decreasing number of blocks. The value of the block is computed using weighted averaging, where the weight of a block is the sum of the weights of the elements in the block. In our example, we wind up with only two blocks, and thus the best fitting monotone function $\hat{z}$ is a step function with a single step from $5/3$ to 4.

The result is plotted in Figure 1. The line through the points x and y is obviously the best possible fitting function. The best fitting monotone function, which we just computed, is the step function consisting of the two horizontal lines.

If x has ties, then this simple algorithm does not apply. There are two straightforward adaptations [2]. In the primary approach to ties, we start our monotone regression with blocks of y values corresponding to the ties in x . Thus, we require tied x values to correspond with tied z values. In the secondary approach, we pose no constraints on tied values, and it can be shown that in that case we merely have to order the y values such that they are increasing

Table 1 Computing monotone regression

y	$\rightarrow$	$\rightarrow$	$\rightarrow$	$\hat{z}$

6	6	6	3	4
0	0	0	3	4

2 Monotonic Regression

Figure 1 Plotting monotone regression

in blocks of tied x values. And then we perform an ordinary monotone regression.

Monotone regression can be generalized in several important directions. First, basically the same algorithm can be used to minimize any separable function of the form $\sum_{i=1}^n f(y_i - z_i)$, with f any convex function with a minimum at zero. For instance, f

can be the absolute value function, in which case we merge blocks by computing medians instead of means. And second, we can generalize the algorithm from weak orders to partial orders in which some elements cannot be compared; for details, see [1]. Finally, it is sometimes necessary to compute the least squares monotone regression with a nondiagonal weight matrix. In this case, the simple block merging algorithms no longer apply, and more general quadratic programming methods must be used.

Monte Carlo Goodness of Fit Tests

Monte Carlo P values

It is often necessary, particularly at a preliminary stage of data analysis, to investigate the compatibility between a known multivariate distribution $\{\pi(x) : x \in S\}$ and a corresponding single observation $x^{(1)} \in S$. Here a ‘single observation’ may mean a vector, perhaps corresponding to a random sample from a univariate distribution, or a table or an image or whatever. In exponential families (see **Generalized Linear Models (GLM)**), the requirement that the distribution is known can be achieved by first conditioning on sufficient statistics so as to eliminate the parameters from the original formulation. In frequentist inference, evidence of a conflict between $x^{(1)}$ and π is quantified by the P value obtained by comparing the observed value $u^{(1)}$ of a particular test statistic $u = u(x)$ with its ‘null distribution’ under π . For small datasets, exact calculations can be made, but usually the null distribution of u is intractable analytically and computationally and so asymptotic chi-squared approximations are invoked. However, such approximations are often invalid because the data are too sparse. This is common in analyzing multidimensional contingency tables; see [1, Section 7.1.5] for a 2^5 table in which the conclusion is questionable.

For definiteness, suppose that $x^{(1)}$ is a table and that relatively large values of $u^{(1)}$ indicate a conflict with π . Then an alternative to the above approach is available if a random sample of tables $x^{(2)}, \dots, x^{(m)}$ can be drawn from π , producing values $u^{(2)}, \dots, u^{(m)}$ of the test statistic u . For if $x^{(1)}$ is indeed from π and ignoring for the moment the possibility of ties, the rank of $u^{(1)}$ among $u^{(1)}, \dots, u^{(m)}$ is uniform on $1, \dots, m$. It follows that, if $u^{(1)}$ turns out to be k th largest among all m values, an exact P value k/m can be declared. This procedure, suggested independently in [2] and [8], is called a *Monte Carlo test*, (see **Monte Carlo Simulation**) though there is sometimes confusion with approximate P values obtained by using simulation to estimate the percentiles of the null distribution of u . Both types of P values converge to the P value in the preceding paragraph as $m \rightarrow \infty$.

The choice of m is governed by computational considerations, with $m = 100$ or 1000 or 10000 the

most popular. Note that, if several investigators carry out the same test on the same data $x^{(1)}$, they will generally obtain slightly different P values, despite the fact that marginally each result is exact! Such differences should not be important at a preliminary stage of analysis and disparities diminish as m increases. Ties between ranks can occur with discrete data, in which case one can quote a corresponding range of P values, though one may also eliminate the problem by using a randomized rule. For detailed investigation of Monte Carlo tests when π corresponds to a random sample of n observations from a population, see [11, 13].

A useful refinement is provided by *sequential* Monte Carlo tests [4] (see **Sequential Testing**). First, one specifies a maximum number of simulations $m - 1$, as before, but now additionally a minimum number h , typically 10 or 20. Then $x^{(2)}, \dots, x^{(m)}$ are drawn sequentially from π but with the proviso that sampling is terminated if ever h of the corresponding $u^{(l)}$'s exceed $u^{(1)}$, in which case a P value h/l is declared, where $l \leq m - 1$ is the number of simulations; otherwise, the eventual P value is k/m , as before. See [3] for the validity of this procedure. Sequential tests encourage early termination when there is no evidence against π but continue sampling and produce a finely graduated P value when the evidence against the model is substantial. For example, if the model is correct and one chooses $m = 1000$ and $h = 20$, the expected sample size is reduced to 98.

For more on simple Monte Carlo tests, see, for example [14]. Such tests have been especially useful in the preliminary analysis of spatial data; see, for example, [5] and [7]. The simplest application occurs in assessing whether a spatial point pattern over a perhaps awkwardly shaped study region A is consistent with a homogeneous Poisson process. By conditioning on the observed number of points n , the test is reduced to one of uniformity in which comparisons are made between the data and $m - 1$ realizations of n points placed entirely at random within A , using any choice of test statistic that is sensitive to interesting departures from the Poisson process.

Markov Chain Monte Carlo P values

Unfortunately, it is not generally practicable to generate samples directly from the target distribution π . For example, this holds even when testing for no

three-way interaction in a three-dimensional **contingency table**: here the face totals are the sufficient statistics but it is not known how to generate random samples from the corresponding conditional distribution, except for very small tables. However, it is almost always possible to employ the Metropolis–Hastings algorithm [12, 16] to construct the transition matrix or kernel P of a Markov chain for which π is a stationary distribution. Furthermore, under the null hypothesis, if one seeds the chain by the data $x^{(1)}$, then the subsequent states $x^{(2)}, \dots, x^{(m)}$ are also sampled from π . This provides an advantage over other Markov Chain Monte Carlo (MCMC) applications in which a burn-in phase is required to achieve stationarity. However, there is now the problem that successive states are dependent and so there is no obvious way in which to devise a legitimate P value for the test. Leaving gaps of r steps, where r is large, between each $x^{(t)}$ and $x^{(t+1)}$ or, in other words, replacing P by P^r , reduces the problem but could still lead to serious bias and, in any case, the goal in MCMC methods is to accommodate the dependence rather than effectively eliminate it, which might require prohibitively long runs (*see Markov Chain Monte Carlo and Bayesian Statistics*).

Two remedies that incorporate dependence and yet retain the exact P values of simple Monte Carlo testing are given in [3]. Both involve running the chain *backwards*, as well as forwards, in time. This is possible for any stationary Markov chain via its corresponding backwards transition matrix or kernel Q and is trivial if P is time reversible, because then $Q = P$. Reversibility can always be arranged but we do not assume it here in describing the simpler of two fixes in [3].

Thus, instead of running the chain forwards, suppose we run it backwards from $x^{(1)}$ for r steps, using Q , to obtain a state $x^{(0)}$, say. The value of the integer r is entirely under our control here. We then run the chain forwards from $x^{(0)}$ for r steps, using P , and do this $m-1$ times independently to obtain states $x^{(2)}, \dots, x^{(m)}$ that are contemporaneous with $x^{(1)}$. It is clear that, if $x^{(1)}$ is a draw from π , then so are $x^{(0)}, x^{(2)}, \dots, x^{(m)}$ but not only this: $x^{(1)}, \dots, x^{(m)}$ have an underlying joint distribution that is exchangeable. Moreover, for any choice of test statistic $u = u(x)$, this property must be inherited by the corresponding $u^{(1)}, \dots, u^{(m)}$. Hence, if $x^{(1)}$ is a draw from π , the rank of $u^{(1)}$ among $u^{(1)}, \dots, u^{(m)}$ is once again uniform and provides an exact P value,

just as for a simple Monte Carlo test. The procedure is rigorous because P values are calculated on the basis of a correct model.

Note that $x^{(0)}$ must be ignored and that also it is not permissible to generate separate $x^{(0)}$'s, else $x^{(2)}, \dots, x^{(m)}$, although exchangeable with each other, are no longer exchangeable with $x^{(1)}$. The value of r should be large enough to provide ample scope for mobility around the state space S , so that simulations can reach more probable parts of S when the formulation is inappropriate. That is, larger values of r tend to improve the power of the test, although the P value itself is valid for any value of r , apart from dealing with ties. Note that it is not essential for validity of the exact P value that P be irreducible. However, this may lead to a loss of power in the test. Irreducibility fails or is in question for many applications to multidimensional contingency tables: the search for better algorithms is currently a hot topic in computational algebra. Finally, see [4] for sequential versions of both procedures in [3].

Example Exact P values for the Rasch Model

Consider an $r \times s$ table of binary variables x_{ij} . For example, in educational testing, $x_{ij} = 0$ or 1 corresponds to the correct (1) or incorrect (0) response of candidate i to item j . See [6] for two well-known LSAT datasets, each with 1000 candidates and 5 questions. For such tables, the **Rasch model** [17] asserts that all responses are independent and that the odds of 1 to 0 in cell (i, j) are $\theta_{ij} : 1$, with $\theta_{ij} = \phi_i \psi_j$, where the ϕ_i 's and ψ_j 's are unknown parameters that can be interpreted as measuring the relative aptitude of the candidates and difficulties of the items, respectively. The probability of a table x is then

$$\prod_{i=1}^r \prod_{j=1}^c \frac{\theta_{ij}^{x_{ij}}}{1 + \theta_{ij}} = \frac{\prod_i \phi_i^{x_{i+}} \prod_j \psi_j^{x_{+j}}}{\prod_i \prod_j (1 + \phi_i \psi_j)} \quad (1)$$

and the row and column totals x_{i+} and x_{+j} are sufficient statistics for the ϕ_i 's and ψ_j 's. Thus, if we condition on the row and column totals, the ϕ_i 's and ψ_j 's are eliminated and we obtain a uniform distribution $\pi(x)$ on the space of tables with the same x_{i+} 's and x_{+j} 's. However, this space is generally huge and enumeration is out of the question; nor are simple Monte Carlo tests available.

Binary tables also occur in evolutionary biology, with x_{ij} identifying presence or absence of species i in location j ; see [10, 15], for example. Here the Rasch model accommodates differences between species and differences between locations, but departures from it can suggest competition between the species.

To construct a test for the Rasch model via MCMC, we require an algorithm that maintains a uniform distribution π on the space S of binary tables x with the same row and column totals as in the data $x^{(1)}$. The simplest move that preserves the margins is depicted below, where $a, b = 0$ or 1 . The two row indices and the two column indices are the same on

$$\begin{array}{ccccccc} & \vdots & & \vdots & & \vdots & \\ \cdots & a & \cdots & b & \cdots & & \\ & \vdots & & \vdots & & \vdots & \\ \cdots & b & \cdots & a & \cdots & & \\ & \vdots & & \vdots & & \vdots & \end{array} \rightarrow \begin{array}{ccccccc} & \vdots & & \vdots & & \vdots & \\ \cdots & b & \cdots & a & \cdots & & \\ & \vdots & & \vdots & & \vdots & \\ \cdots & a & \cdots & b & \cdots & & \\ & \vdots & & \vdots & & \vdots & \end{array}$$

the right as on the left. Of course, there is no change in the configuration unless $a \neq b$. It can be shown that any table in S can be reached from any other by a sequence of such switches, so that irreducibility is guaranteed. Among several possible ways in which the algorithm can proceed (see [3]), the simplest is to repeatedly choose two rows and two columns at random and to propose the corresponding swap if this is valid or retain the current table if it is not. This defines a Metropolis algorithm and, since π is uniform, all proposals are accepted.

Closing Comments

We close with some brief additional comments on MCMC tests. As regards the test statistic $u(x)$, the choice should reflect the main alternatives that one has in mind. For example, in educational testing, interest might center on departures from the Rasch model caused by correlation between patterns of correct or incorrect responses to certain items. Then $u(x)$ might be a function of the *coincidence matrix*, whose (j, j') element is the frequency with which candidates provide the same response to items j and j' . Corresponding statistics are easy to define and can provide powerful tools, but note that the total score in the matrix is no use because it is fixed by the row and column totals of the data. For ecologic applications, [10] provides an interesting discussion and advocates using a statistic based on the *co-occurrence matrix*.

Second, it is often natural to apply several different statistics to the same data: there is no particular objection to this at an exploratory stage, provided that all the results are reported. Finally, we caution against some misleading claims. Thus, the Knight's move algorithm [18] for the Rasch model is simply incorrect: see [10]. Also, some MCMC tests are referred to as 'exact' when in fact they do not apply either of the corrections described in [3] and are therefore approximations; see [9], for example.

Monte Carlo Simulation

Introduction

Monte Carlo methods use random processes to estimate mathematical or physical quantities, to study distributions of random variables, to study and compare statistical procedures, and to study the behavior of complex systems. Monte Carlo methods had been used occasionally by statisticians for many years, but with the development of high-speed computers, Monte Carlo methods became viable alternatives to theoretical and experimental methods in studying complicated physical processes. The random samples used in a Monte Carlo method are generated on the computer, and are more properly called “pseudorandom numbers”.

An early example of how a random process could be used to evaluate a fixed mathematical quantity is the Buffon needle problem. The French naturalist Comté de Buffon showed that the probability that a needle of length l thrown randomly onto a grid of parallel lines with distance d ($\geq l$) apart intersects a line is $2l/(\pi d)$. The value of π can, therefore, be estimated by tossing a needle onto a lined grid many times and counting the number of times the needle crosses one of the lines. (See [2], pp. 274, 275 for discussion of the problem and variations on the method.) A key element of the Buffon needle problem is that there is no intrinsic random element; randomness is introduced to study the deterministic problem of evaluating a mathematical constant.

The idea of simulating a random process to study its distributional properties is so basic and straightforward that these methods were used in very early studies of probability distributions. An early documented use of a Monte Carlo method was by the American statistician Erastus Lyman De Forest in 1876 in a study of smoothing a time series (see [4]). Another important early use of Monte Carlo was by “Student” (see **Gosset, William Sealy**) in studying the distributions of the correlation coefficient and of the t statistic (see **Catalogue of Probability Density Functions**). Student used actual biometric data to simulate realizations of normally distributed random variables.

Monte Carlo Evaluation of an Integral

In its simplest form, Monte Carlo simulation is the evaluation of a definite integral

$$\theta = \int_D f(x) \, dx \quad (1)$$

by identifying a random variable Y with support on D and density $p(y)$ and a function g such that the expected value of $g(Y)$ is θ :

$$\begin{aligned} E(g(Y)) &= \int_D g(y)p(y) \, dy \\ &= \int_D f(y) \, dy \\ &= \theta. \end{aligned} \quad (2)$$

In the simplest case, D is the interval $[a, b]$, Y is taken to be a random variable with a uniform density over $[a, b]$; that is, $p(y)$ in (2) is the constant uniform density. In this case,

$$\theta = (b - a)E(f(Y)). \quad (3)$$

The problem of evaluating the integral becomes the familiar statistical problem of estimating a mean, $E(f(Y))$. From a sample of size m , a good estimate of θ is the sample mean,

$$\hat{\theta} = (b - a) \frac{\sum_{i=1}^m f(y_i)}{m}, \quad (4)$$

where the y_i are values of a random sample from a uniform distribution over (a, b) . The estimate is unbiased (see **Estimation**):

$$\begin{aligned} E(\hat{\theta}) &= (b - a) \frac{\sum E(f(Y_i))}{m} \\ &= (b - a)E(f(Y)) \\ &= \int_a^b f(x) \, dx. \end{aligned} \quad (5)$$

The variance is

$$V(\hat{\theta}) = (b - a)^2 \frac{\sum V(f(Y_i))}{m^2}$$

2 Monte Carlo Simulation

$$\begin{aligned}
 &= \frac{(b-a)^2}{m} V(f(Y)) \\
 &= \frac{(b-a)}{m} \int_a^b \left(f(x) - \int_a^b f(t) dt \right)^2 dx. \quad (6)
 \end{aligned}$$

The integral in (6) is a measure of the *roughness* of the function.

Consider again the problem of evaluation of the integral in (1) that has been rewritten as in (2). Now suppose that we can generate m random variates y_i from the distribution with density p . Then our estimate of θ is just

$$\hat{\theta} = \frac{\sum g(y_i)}{m}. \quad (7)$$

Compare this estimator with the estimator in (4).

The use of a probability density as a weighting function allows us to apply the Monte Carlo method to improper integrals (that is, integrals with infinite ranges of integration). The first thing to note, therefore, is that the estimator (7) applies to integrals over general domains, while the estimator (4) applies only to integrals over finite intervals. Another important difference is that the variance of the estimator in (7) is likely to be smaller than that of the estimator in (4).

The square root of the variance (that is, the standard deviation of the estimator) is a good measure of the range within which different realizations of the estimator of the integral may fall. Under certain assumptions, using the standard deviation of the estimator, we can define statistical “**confidence intervals**” for the true value of the integral θ . Loosely speaking, a confidence interval is an interval about an estimator $\hat{\theta}$ that in repeated sampling would include the true value θ a specified portion of the time. (The specified portion is the “level” of the confidence interval and is often chosen to be 90% or 95%. Obviously, all other things being equal, the higher the level of confidence, the wider the interval must be.)

Because of the dependence of the confidence interval on the standard deviation, the standard deviation is sometimes called a “probabilistic error bound”. The word “bound” is misused here, of course, but in any event, the standard deviation does provide some measure of a sampling “error”.

From (6), we note that the order of error in terms of the Monte Carlo sample size is $O(m^{-1/2})$. This results in the usual diminished returns of ordinary

statistical estimators; to halve the error, the sample size must be quadrupled.

An important property of the standard deviation of a Monte Carlo estimate of a definite integral is that the order in terms of the number of function evaluations is independent of the dimensionality of the integral. On the other hand, the usual error bounds for numerical quadrature are $O(m^{-2/d})$, where d is the dimensionality. For one or two dimensions, it is generally better to use one of the standard methods of numerical quadrature, such as Newton–Cotes methods, extrapolation or Romberg methods, and Gaussian quadrature, rather than Monte Carlo quadrature.

Experimental Error in Monte Carlo Methods

Monte Carlo methods are sampling methods; therefore, the estimates that result from Monte Carlo procedures have associated *sampling errors*. The fact that the estimate is not equal to its expected value (assuming that the estimator is unbiased) is not an “error” or a “mistake”; it is just a result of the variance of the random (or pseudorandom) data. Monte Carlo methods are experiments using random data. The variability of the random data results in *experimental error*, just as in other scientific experiments in which randomness is a recognized component.

As in any statistical estimation problem, an estimate should be accompanied by an estimate of its variance. The estimate of the variance of the estimator of interest is usually just the sample variance of computed values of the estimator of interest.

Following standard practice, we could use the square root of the variance (that is, the standard deviation) of the Monte Carlo estimator to form an approximate confidence interval for the integral being estimated.

In reporting numerical results from Monte Carlo simulations, it is mandatory to give some statement of the level of the experimental error. An effective way of doing this is by giving the sample standard deviation. When a number of results are reported, and the standard deviations vary from one to the other, a good way of presenting the results is to write the standard deviation in parentheses beside the result itself, for example,

$$3.147 (0.0051).$$

Notice that if the standard deviation is of order 10^{-3} , the precision of the main result is not greater than 10^{-3} . Just because the computations are done at a higher precision is no reason to write the number as if it had more significant digits.

Variance of Monte Carlo Estimators

The variance of a Monte Carlo estimator has important uses in assessing the quality of the estimate of the integral. The expression for the variance, as in (6), is likely to be very complicated and to contain terms that are unknown. We therefore need methods for estimating the variance of the Monte Carlo estimator.

A Monte Carlo estimate usually has the form of the estimator of θ in (4):

$$\hat{\theta} = c \frac{\sum f_i}{m}. \quad (8)$$

The variance of the estimator has the form of (6):

$$V = (\hat{\theta})^2 c^2 \int \left(f(x) - \int f(t) dt \right)^2 dx.$$

An estimator of the variance is

$$\hat{V}(\hat{\theta}) = c^2 \frac{\sum (f_i - \bar{f})^2}{m-1}. \quad (9)$$

This estimator is appropriate only if the elements of the set of random variables $\{F_i\}$, on which we have observations $\{f_i\}$, are (assumed to be) independent and thus have zero correlations.

Our discussion of variance in Monte Carlo methods that are based on pseudorandom numbers follows the pretense that the numbers are realizations of random variables, and the main concern in pseudorandom number generation is the simulation of a sequence of i.i.d. random variables. In quasirandom number generation, the attempt is to get a sample that is spread out over the sample space more evenly than could be expected from a random sample. Monte Carlo methods based on quasirandom numbers, or “quasi-Monte Carlo” methods, do not admit discussion of variance in the technical sense.

Variance Reduction

An objective in sampling is to reduce the variance of the estimators while preserving other good qualities, such as unbiasedness. Variance reduction results in statistically efficient estimators. The emphasis on efficient Monte Carlo sampling goes back to the early days of digital computing, but the issues are just as important today (or tomorrow) because, presumably, we are solving bigger problems. The general techniques used in statistical sampling apply to Monte Carlo sampling, and there is a mature theory for sampling designs that yield efficient estimators.

Except for straightforward analytic reduction, discussed in the next section, techniques for reducing the variance of a Monte Carlo estimator are called “swindles” (especially if they are thought to be particularly clever). The common thread in variance reduction is to use additional information about the problem in order to reduce the effect of random sampling on the variance of the observations. This is one of the fundamental principles of all statistical design.

Analytic Reduction

The first principle in estimation is to use any known quantity to improve the estimate. For example, suppose that the problem is to evaluate the integral

$$\theta = \int_D f(x) dx \quad (10)$$

by Monte Carlo methods. Now, suppose that D_1 and D_2 are such that $D_1 \cup D_2 = D$ and $D_1 \cap D_2 = \emptyset$, and consider the representation of the integral

$$\begin{aligned} \theta &= \int_{D_1} f(x) dx + \int_{D_2} f(x) dx \\ &= \theta_1 + \theta_2. \end{aligned} \quad (11)$$

Now, suppose that a part of this decomposition of the original problem is known (that is, suppose that we know θ_1). It is very likely that it would be better to use Monte Carlo methods only to estimate θ_2 and take as our estimate of θ the sum of the known θ_1 and the estimated value of θ_2 . This seems intuitively obvious, and it is generally true unless there is some relationship between $f(x_1)$ and $f(x_2)$, where x_1 is in D_1 and x_2 is in D_2 . If there is some known relationship, however, it may be possible to improve

4 Monte Carlo Simulation

the estimate $\hat{\theta}_2$ of θ_2 by using a transformation of the same random numbers used for $\hat{\theta}_1$ to estimate θ_1 . For example, if $\hat{\theta}_1$ is larger than the known value of θ_1 , the proportionality of the overestimate, $(\hat{\theta}_1 - \theta_1)/\theta_1$, may be used to adjust $\hat{\theta}_2$. This is the same principle as ratio or regression estimation in ordinary sampling theory.

Stratified Sampling and Importance Sampling

In stratified sampling (see **Stratification**), certain proportions of the total sample are taken from specified regions (or “strata”) of the sample space. The objective in stratified sampling may be to ensure that all regions are covered. Another objective is to reduce the overall variance of the estimator by sampling more heavily where the function is rough; that is, where the values $f(x_i)$ are likely to exhibit a lot of variability.

Stratified sampling is usually performed by forming distinct subregions with different importance functions in each. This is the same idea as in analytic reduction except that Monte Carlo sampling is used in each region.

Stratified sampling is based on exactly the same principle in sampling methods in which the allocation is proportional to the variance (see [3]). In some of the literature on Monte Carlo methods, stratified sampling is called “geometric splitting”.

In *importance sampling*, just as may be the case in stratified sampling, regions corresponding to large values of the integrand are sampled more heavily. In importance sampling, however, instead of a finite number of regions, we allow the relative sampling density to change continuously. This is accomplished by careful choice of p in the decomposition implied by (2). We have

$$\begin{aligned}\theta &= \int_D f(x) dx \\ &= \int_D \frac{f(x)}{p(x)} p(x) dx,\end{aligned}\quad (12)$$

where $p(x)$ is a probability density over D . The density $p(x)$ is called the *importance function*. Stratified sampling can be thought of as importance sampling in which the importance function is composed of a mixture of densities. In some of the literature on Monte Carlo methods, stratified sampling and importance sampling are said to use “weight windows”.

From a sample of size m from the distribution with density p , we have the estimator,

$$\hat{\theta} = \frac{1}{m} \sum \frac{f(x_i)}{p(x_i)}. \quad (13)$$

Generating the random variates from the distribution with density p weights the sampling into regions of higher probability with respect to p . By judicious choice of p , we can reduce the variance of the estimator.

The variance of the estimator is

$$V(\hat{\theta}) = \frac{1}{m} V\left(\frac{f(X)}{p(X)}\right), \quad (14)$$

where the variance is taken with respect to the distribution of the random variable X with density $p(x)$. Now,

$$V\left(\frac{f(X)}{p(X)}\right) = E\left(\frac{f^2(X)}{p^2(X)}\right) - \left(E\left(\frac{f(X)}{p(X)}\right)\right)^2. \quad (15)$$

The objective in importance sampling is to choose p so that this variance is minimized. Because

$$\left(E\left(\frac{f(X)}{p(X)}\right)\right)^2 = \left(\int_D f(x) dx\right)^2, \quad (16)$$

the choice involves only the first term in the expression for the variance. By Jensen’s inequality, we have a lower bound on that term:

$$\begin{aligned}E\left(\frac{f^2(X)}{p^2(X)}\right) &\geq \left(E\left(\frac{|f(X)|}{p(X)}\right)\right)^2 \\ &= \left(\int_D |f(x)| dx\right)^2.\end{aligned}\quad (17)$$

That bound is obviously achieved when

$$p(x) = \frac{|f(x)|}{\int_D |f(x)| dx}. \quad (18)$$

Of course, if we knew $\int_D |f(x)| dx$, we would probably know $\int_D f(x) dx$ and would not even be considering the Monte Carlo procedure to estimate the integral. In practice, for importance sampling we would seek a probability density p that is nearly proportional to $|f|$; that is, such that $|f(x)|/p(x)$ is nearly constant.

The problem of choosing an importance function is very similar to the problem of choosing a majorizing function for the acceptance/rejection method. Selection of an importance function involves the principles of function approximation with the added constraint that the approximating function be a probability density from which it is easy to generate random variates.

Let us now consider another way of developing the estimator (13). Let $h(x) = f(x)/p(x)$ (where $p(x)$ is positive; otherwise, let $h(x) = 0$) and generate $y_1, \dots, y_m$ from a density $g(y)$ with support D . Compute *importance weights*,

$$w_i = \frac{p(y_i)}{g(y_i)}, \quad (19)$$

and form the estimate of the integral as

$$\hat{\theta} = \frac{1}{m} \frac{\sum w_i h(y_i)}{\sum w_i}. \quad (20)$$

In this form of the estimator, $g(y)$ is a trial density, just as in the acceptance/rejection methods. This form of the estimator has similarities to weighted resampling.

By the same reasoning as above, we see that the trial density should be “close” to f ; that is, optimally, $g(x) = c|f(x)|$ for some constant c .

Although the variance of the estimator in (13) and (20) may appear rather simple, the term $E((f(X)/p(X))^2)$ could be quite large if p (or g) becomes small at some point where f is large. Of course, the objective in importance sampling is precisely to prevent that, but if the functions are not well-understood, it may happen. An element of the Monte Carlo sample at a point where p is small and f is large has an unduly large influence on the overall estimate. Because of this kind of possibility, importance sampling must be used with some care. (See [2], chapter 7, for further discussion the method.)

Use of Covariates

Another way of reducing the variance, just as in ordinary sampling, is to use covariates. Any variable that is correlated with the variable of interest has potential value in reducing the variance of the estimator. Such a variable is useful if it is easy to generate and

if it has properties that are known or that can be computed easily. In the general case in Monte Carlo sampling, covariates are called control variates. Two special cases are called antithetic variates and common variates. We first describe the general case, and then the two special cases. We then relate the use of covariates to the statistical method sometimes called “Rao-Blackwellization”.

Control Variates. Suppose that Y is a random variable, and the Monte Carlo method involves estimation of $E(Y)$. Suppose that X is a random variable with known expectation, $E(X)$, and consider the random variable

$$\tilde{Y} = Y - b(X - E(X)). \quad (21)$$

The expectation of $\tilde{Y}$ is the same as that of Y , and its variance is

$$V(\tilde{Y}) = V(Y) - 2b\text{Cov}(Y, X) + b^2V(X). \quad (22)$$

For reducing the variance, the optimal value of b is $\text{Cov}(Y, X)/V(X)$. With this choice $V(\tilde{Y}) < V(Y)$ as long as $\text{Cov}(Y, X) \neq 0$. Even if $\text{Cov}(Y, X)$ is not known, there is a b that depends only on the sign of $\text{Cov}(Y, X)$ for which the variance of $\tilde{Y}$ is less than the variance of Y .

The variable X is called a *control variate*. This method has long been used in survey sampling, where $\tilde{Y}$ in (21) is called a regression estimator.

Use of these facts in Monte Carlo methods requires identification of a control variable X that can be simulated simultaneously with Y . If the properties of X are not known but can be estimated (by Monte Carlo methods), the use of X as a control variate can still reduce the variance of the estimator.

These ideas can obviously be extended to more than one control variate:

$$\begin{aligned} \tilde{Y} = & Y - b_1(X_1 - E(X_1)) - \dots \\ & - b_k(X_k - E(X_k)). \end{aligned} \quad (23)$$

The optimal values of the b_i s depend on the full variance-covariance matrix. The usual regression estimates for the coefficients can be used if the variance-covariance matrix is not known.

Identification of appropriate control variates often requires some ingenuity, although in some special cases, there may be techniques that are almost always applicable.

Antithetic Variates. Again consider the problem of estimating the integral

$$\theta = \int_a^b f(x) dx \quad (24)$$

by Monte Carlo methods. The standard crude Monte Carlo estimator, (4), is $(b-a) \sum f(x_i)/n$, where x_i is uniform over (a, b) . It would seem intuitively plausible that our estimate would be subject to less sampling variability if, for each x_i , we used its “mirror”

$$\tilde{x}_i = a + (b - x_i). \quad (25)$$

This mirror value is called an antithetic variate, and use of antithetic variates can be effective in reducing the variance of the Monte Carlo estimate, especially if the integral is nearly uniform. For a sample of size n , the estimator is

$$\frac{b-a}{n} \sum_{i=1}^n (f(x_i) + f(\tilde{x}_i)).$$

The variance of the sum is the sum of the variances plus twice the covariance. Antithetic variates have negative covariances, thus reducing the variance of the sum.

Antithetic variates from distributions other than the uniform can also be formed. The linear transformation that works for uniform antithetic variates cannot be used, however. A simple way of obtaining negatively correlated variates from other distributions is just to use antithetic uniforms in the inverse CDF. If the variates are generated using acceptance/rejection, antithetic variates can be used in the majorizing distribution.

Common Variates. Often, in Monte Carlo simulation, the objective is to estimate the differences in parameters of two random processes. The two parameters are likely to be positively correlated. If that is the case, then the variance in the individual differences is likely to be smaller than the variance of the difference of the overall estimates.

Suppose, for example, that we have two statistics, T and S , that are unbiased estimators of some parameter of a given distribution. We would like to know the difference in the variances of these estimators,

$$V(T) - V(S)$$

(because the one with the smaller variance is better). We assume that each statistic is a function of a

random sample: $\{x_1, \dots, x_n\}$. A Monte Carlo estimate of the variance of the statistic T for a sample of size n is obtained by generating m samples of size n from the given distribution, computing T_i for the i th sample, and then computing

$$\hat{V}(T) = \frac{\sum_{i=1}^m (T_i - \bar{T})^2}{m-1}. \quad (26)$$

Rather than doing this for T and S separately, using the unbiasedness, we could first observe

$$V(T) - V(U) = E(T^2) - E(S^2) = E(T^2 - S^2) \quad (27)$$

and hence estimate the latter quantity. Because the estimators are likely to be positively correlated, the variance of the Monte Carlo estimator $\hat{E}(T^2 - S^2)$ is likely to be smaller than the variance of $\hat{V}(T) - \hat{V}(S)$. If we compute $T^2 - S^2$ from each sample (that is, if we use *common variates*), we are likely to have a more precise estimate of the difference in the variances of the two estimators, T and S .

Rao-Blackwellization. As in the discussion of control variates above, suppose that we have two random variables Y and X and we want to estimate $E(f(Y, X))$ with an estimator of the form $T = \sum f(Y_i, X_i)/m$. Now suppose that we can evaluate $E(f(Y, X)|X = x)$. (This is similar to what is done in using (21) above.) Now, $E(E(f(Y, X)|X = x)) = E(f(Y, X))$, so the estimator

$$\tilde{T} = \sum \frac{E(f(Y_i, X)|X = x_i)}{m} \quad (28)$$

has the same expectation as T . However, we have

$$V(f(Y, X)) = V(E(f(Y, X)|X = x)) + E(V(f(Y, X)|X = x)); \quad (29)$$

that is,

$$V(f(Y, X)) \geq V(E(f(Y, X)|X = x)). \quad (30)$$

Therefore, $\tilde{T}$ is preferable to T because it has the same expectation but no larger variance. (The function f may depend on Y only. In that case, if Y and X are independent we can gain nothing.)

The principle of minimum variance unbiased estimation leads us to consider statistics such as $\tilde{T}$ conditioned on other statistics. The Rao-Blackwell

Theorem (see any text on mathematical statistics) tells us that if a sufficient statistic exists, the greatest improvement in variance while still requiring unbiasedness occurs when the conditioning is done with respect to a sufficient statistic. This process of conditioning a given estimator on another statistic is called Rao-Blackwellization. (This name is often used even if the conditioning statistic is not sufficient.)

Applications of Monte Carlo Simulation

Monte Carlo simulation is widely used in many fields of science and business. In the physical sciences, Monte Carlo methods were first employed on a major scale in the 1940s, and their use continues to grow. System simulation has been an important methodology in operations research since the 1960s. In more recent years, simulation of financial processes has become an important tool in the investments industry.

Monte Carlo simulation has two distinct applications in statistics. One is in the study of statistical methods, and the other is as a part of a statistical method for analysis of data.

Monte Carlo Studies of Statistical Methods. The performance of a statistical method, such as a t Test, for example, depends, among other things, on the underlying distribution of the sample to which it is applied. For simple distributions and for simple statistical procedures, it may be possible to work out analytically such things as the power of a test or the exact distribution of a test statistic or estimator. In more complicated situations, however, these properties cannot be derived analytically. The properties can be studied by Monte Carlo, however. The procedure is simple; we merely simulate on the computer many samples from the assumed underlying distribution, compute the statistic of interest from each sample, and use the sample of computed statistics to assess its sampling distribution. There is a wealth of literature and software for the generation of random numbers required in first step in this process (see, for example, [2]).

Monte Carlo simulation to study statistical methods is most often employed in the comparison of methods, frequently in the context of robustness studies. It is relatively easy to compare the relative performance of say a t Test with a sign test under a

wide range of scenarios by generating multiple samples under each scenario and evaluating the t Test and the sign test for each sample in the given scenario.

This application of Monte Carlo simulation is so useful that it is employed by a large proportion of the research articles published in statistics. (In the 2002 volume of the *Journal of the American Statistical Association*, for example, more than 80% of the articles included Monte Carlo (see **Bayesian Statistics**) studies of the performance of the statistical methods.)

Monte Carlo Methods in Data Analysis. In computational statistics, Monte Carlo methods are used as part of the overall methodology of data analysis. Examples include Monte Carlo tests, Monte Carlo **bootstrapping**, and **Markov chain Monte Carlo** for the evaluation of Bayesian posterior distributions.

A Monte Carlo test of an hypothesis, just as any statistical hypothesis test, uses a random sample of observed data. As with any statistical test, a test statistic is computed from the observed sample. In the usual statistical tests, the computed test statistic is compared with the quantiles of the distribution of the test statistic under the null hypothesis, and the null hypothesis is rejected if the computed value is deemed sufficiently extreme. Often, however, we may not know the distribution of the test statistic under the null hypothesis. In this case, if we can simulate random samples from a distribution specified by the null hypothesis, we can simulate the distribution of the test statistic by generating many such samples, and computing the test statistic for each one. We then compare the observed value of the test statistic with the ones computed from the simulated random samples. Just as in the standard methods of statistical hypothesis testing, we reject the null hypothesis if the observed value of the test statistic is deemed sufficiently extreme. This is called a Monte Carlo test. Somewhat surprisingly, a Monte Carlo test needs only a fairly small number of random samples to be relatively precise. In most cases, only 100 or so samples are adequate. See chapters 2 through 4 of [1] for further discussion of Monte Carlo tests and other Monte Carlo methods in statistical data analysis.

Multidimensional Item Response Theory Models

Many educational and psychological tests are inherently multidimensional, meaning these tests measure two or more dimensions or constructs [27]. A construct is a theoretical representation of the underlying trait, concept, attribute, processes, and/or structure that the test is designed to measure [16]. Tests that are composed of items each measuring the same construct, or same composite of multiple constructs, are considered to be unidimensional. If, however, different items are measuring different constructs, or different composites of multiple constructs, the test can be considered to be multidimensional. It is important to distinguish between construct-irrelevant or invalid traits that are being measured versus those traits that are valid and replicable [5].

If a test is unidimensional, then it is appropriate to report examinee performance on the test as a single score. If a test is multidimensional, then reporting examinee results is more problematic. In some cases, if the skills are distinct, a profile of scores may be most appropriate. If the items are measuring similar composites of skills, then a single score may suffice. Problems of how to report results can easily arise. For example, consider a test in which easy items measure skill A and difficult items measure skill B. If the results of this test are reported on a single score scale, comparing results could be impossible because low scores represent differences in skill A and high scores represent differences in skill B.

Response data represent the interaction between a group of examinees and a set of items. Surprisingly, an assessment can be either unidimensional or multidimensional depending on the set of skills inherent in a particular group of examinees who take the test. Consider the following two items:

Item 1: If $500 - 4X = 138$, then $X = ?$

Item 2: Janelle went to the store and bought four pieces of candy. She gave the clerk \$5.00 and received \$1.38 back. How much did one piece of candy cost?

Item 1 requires the examinee to use algebra to solve the linear equation. Item 2, a ‘story problem’, requires the examinee to read the scenario, translate the text to an algebraic expression, and then solve. If examinees vary in the range of reading skill required to read and translate the text in item 2, then the item has the potential to measure a composite of both reading and algebra. If all the examinees vary in reading skill, but in a range beyond the level of reading required by item 2, then this item will most likely distinguish only between levels of examinee proficiency in algebra.

One item is always unidimensional. However, two or more items, each measuring a different composite of, say, algebra and reading, have the potential to yield multidimensional data. Ironically, the same items administered to one group of examinees may result in unidimensional data, yet when given to another group of examinees, may yield multidimensional data.

Determining if Data are Multidimensional

The first step in any multidimensional item response theory (MIRT) analysis (*see Item Response Theory (IRT) Models for Dichotomous Data*) is to determine whether the data are indeed multidimensional. Dimensionality and MIRT analyses should be supported by, and perhaps even preempted with, substantive judgment. A thorough analysis of the knowledge and skills needed to successfully respond to each item should be conducted. It might be helpful to conduct this substantive analysis by referring to the test specifications and the opinions of experts who have extensive knowledge of the content and of the examinees’ cognitive skills. If subsets of items measure different content knowledge and/or cognitive skills, then these items have the potential to represent distinct dimensions if given to a group of examinees that vary on these skills.

Many empirical methods have been proposed to investigate the dimensionality of test data (e.g., [10, 11]). These quantitative methods range from linear factor analysis to several nonparametric methods [9, 12, 17, 18, 25, 32]. Unfortunately, most of the dimensionality tools available to practitioners are exploratory in nature, and many of these tools produce results that contradict substantive dimensionality hypotheses [10].

Factor analysis is a data reduction technique that uses the inter-item correlations to distinguish a small set of underlying skills or factors. A factor can be substantively identified by noting which items load highly on the factor. Additionally, scree plots of **eigenvalues** can be used to determine if more than one factor is necessary to account for the total variance observed in the test scores. Unfortunately, there is no one method that psychometricians can agree upon to determine how large eigenvalues have to be to indicate a set of test data are indeed multidimensional.

A nonparametric approach that some researchers have found useful is **hierarchical cluster analysis** [21]. This approach uses proximity matrices (*see Proximity Measures*) and clustering rules to form homogeneous groups of items. This is an iterative procedure. For an n -item test, the procedure will form n -clusters, then $n - 1$ cluster, and so on until all the items are combined into a single cluster. Researchers often examine the two- or three-cluster solutions to determine if these solutions define identifiable traits. One drawback with this approach is that because the solution for each successive iteration of the algorithm is dependent on the previous solution, the solution attained at one or more levels may not be optimal.

A relatively new approach is a procedure called *DETECT* [32]. *DETECT* is an exploratory nonparametric dimensionality assessment procedure that estimates the number of dominant dimensions present in a data set and the magnitude of the departure from unidimensionality using a genetic algorithm. *DETECT* also identifies the dominant dimension measured by each item. This procedure produces mutually exclusive, dimensionally homogeneous clusters of items.

Perhaps one of the more promising nonparametric approaches for determining if two groups of items are dimensionally distinct is the program *DIMTEST* based on the work of Stout [24]. Hypotheses about multiple dimensions that are formulated using substantive analysis, factor analysis, cluster analysis, or *DETECT* can be tested using *DIMTEST*. This program provides a statistical test of significance, which can verify that test data are not unidimensional. Once it has been determined that the test data are multidimensional, practitioners need to determine which multidimensional model best describes the response process for predicting correct response on the individual items.

MIRT Models

Reckase [19] defined the probability of a correct response for subject j on item i on a compensatory model as

$$P_C(u_{ij} = 1 | \theta_{j1}, \theta_{j2}) = \frac{1}{1 + e^{a_{i1}\theta_{j1} + a_{i2}\theta_{j2} + d_j}} \quad (1)$$

where u_{ij} is the dichotomous score (0 = wrong, 1 = correct),

θ_{j1} and θ_{j2} are the two ability parameters for dimensions 1 and 2,

a_{i1} and a_{i2} are the item discrimination parameters for dimensions 1 and 2,

d_j is the scalar difficulty parameter.

Even though there is a discrimination parameter for each dimension, there is only one difficulty parameter. That is, difficulty parameters for each dimension are indeterminate. Reckase called the model M2PL because it was a two-dimensional version of the two-parameter (discrimination and difficulty) unidimensional item response theory (IRT) model.

In a two-dimensional latent ability space, the a_i vector designates the $\theta_1 - \theta_2$ combination that is being best measured (i.e., the composite for which the item can optimally discriminate). If $a_1 = a_2$, both dimensions are measured equally well. If $a_1 = 0$ and $a_2 > 0$, discrimination only occurs along the θ_1 .

Graphically, for an item, the M2PL model probability of correct response forms an item response surface as opposed to the unidimensional item characteristic curve. Four different perspectives of this surface for an item with $a_1 = 1.0$, $a_2 = 1.0$, and $d = 0.20$ is illustrated in Figure 1.

The reason the M2PL model is denoted as a compensatory model is due to the addition of terms in the logit. This feature makes it possible for an examinee with low ability on one dimension to compensate by having a higher probability on the remaining dimension. Figure 2 illustrates the equiprobability contours for the response surface of the item shown in Figure 1. For the compensatory model, the contours are equally spaced and parallel across the response surface. The contour lines become closer as the slope of the response surface becomes steeper or more discriminating. Notice that Examinee A (high θ_1 , low θ_2) has the same probability of correct response as Examinee B (high θ_2 , low θ_1). Note,

Figure 1 Four perspectives of a compensatory response surface

Figure 2 The contour plot of a compensatory item response surface with equal discrimination parameters

4 Multidimensional IRT Models

however, that the degree of compensation is greatest when $a_1 = a_2$. Obviously, the more a_1 and a_2 differ (e.g., $a_1 = 0$ and $a_2 > 0$, or $a_2 = 0$ and $a_1 > 0$), the less compensation can occur. That is, for integration of skills to be possible, an item must require the use of both skills.

Another multidimensional model that researchers have investigated is the noncompensatory model, proposed by Sympson [26]. This model (also known as the partial compensatory model) expresses the probability of correct response for subject j on item i as,

$$P(u_{ij} = 1 | \theta_{j1}, \theta_{j2}) = \left[\frac{1}{1 + e^{-a_{i1}(\theta_{j1} - b_{i1})}} \right] \times \left[\frac{1}{1 + e^{-a_{i2}(\theta_{j2} - b_{i2})}} \right] \quad (2)$$

where u_{ij} is the dichotomous score (0 = wrong, 1 = correct),

θ_{j1} and θ_{j2} are the two ability parameters for dimensions 1 and 2,

a_{i1} and a_{i2} are the item discrimination parameters for dimensions 1 and 2,

b_{i1} and b_{i2} are the item difficulty parameters for dimensions 1 and 2.

This model is essentially the product of two 2PL unidimensional IRT models, the overall probability of a correct response is bounded in the upper limit by the smaller of the two component probabilities. A graph of the item characteristic surface for an item with parameters $a_1 = 1.0$, $a_2 = 1.0$, $b_1 = 0.0$ and $b_2 = 0.0$ is shown in Figure 3.

Examining the contour plot for this item, Figure 4, enables one to see the noncompensatory nature of the model. Note that Examinee A (high θ_1 , low θ_2), and Examinee B (low θ_1 , high θ_2) have approximately the same probability as Examinee C (low θ_1 , low θ_2), indicating that little compensation actually occurs. It should be noted that the noncompensatory surface actually curves around, creating the curvilinear equiprobability contours shown in Figure 4.

Spray, Ackerman, and Carlson [23] extended the work of Reckase and Sympson by formulating a generalized MIRT model that combined both the compensatory and noncompensatory models. Letting

Figure 3 Four perspectives of a noncompensatory response surface

Figure 4 The contour plot of a noncompensatory response surface

$f_1 = a_1(\theta_1 - b_1)$ and $f_2 = a_2(\theta_2 - b_2)$, the compensatory model (1) can be written as

$$P_C = \frac{e^{(f_1+f_2)}}{1 + e^{(f_1+f_2)}} \quad (3)$$

and the noncompensatory model (4) can be written as

$$P_{NC} = \frac{e^{(f_1+f_2)}}{[1 + e^{(f_1+f_2)}] + e^{f_1} + e^{f_2}}. \quad (4)$$

The generalized model can then be expressed as

$$P_G = \frac{e^{(f_1+f_2)}}{[1 + e^{(f_1+f_2)}] + \mu[e^{f_1} + e^{f_2}]} \quad (5)$$

where μ represents a compensation or integration parameter that ranges from 0 to 1. If $\mu = 0$, then P_G is equivalent to the compensatory model (1), and if $\mu = 1$, then P_G is equivalent to the noncompensatory (2). As μ increases from 0, the degree of compensation decreases, and the equiprobability contours become more curvilinear. Contour plots for μ -parameter of 0.1 and 0.3 are shown in Figure 5.

For a more comprehensive development of different types of item response theory models, both unidimensional and multidimensional, readers are referred to van der Linden and Hambleton [28].

Figure 5 A contour of a generalized model response surface with $\mu = 0.15$

Estimating Item and Ability Parameters

Several software estimation programs were developed to estimate item parameters for the compensatory model, including NOHARM [8] and TESTFACT [30]. NOHARM uses a nonlinear factor analytic approach [14, 15], and can estimate item parameters for models having from one to six dimensions. It has both an exploratory or confirmatory mode (*see Factor Analysis: Confirmatory*). Unfortunately, NOHARM does not have the capability to estimate examinees' ability levels. TESTFACT uses a full-information approach to estimating both item and ability parameters for multidimensional compensatory models.

A relatively new approach using **Markov chain Monte Carlo** procedure was used by Bolt and Lall [6] to estimate parameters for both the compensatory and noncompensatory models. This estimation approach was used to estimate the degree of compensation in the generalized model by Ackerman and Turner [4], though with limited success. Another interesting approach using the genetic algorithm used in the program DETECT has been proposed by Zhang [31] to estimate parameters for the noncompensatory model. To date, there has been very little research on the goodness-of-fit of multidimensional models. One exception is the work of Ackerman,

Hombo, and Neustel [3], which looked at goodness-of-fit measures using the compensatory model.

Graphical Representations of Multidimensional Items and Information

To better understand and interpret MIRT item parameters, practitioners can use a variety of graphical techniques [2]. Item characteristic surface plots and contour plots do not allow the practitioner to examine and compare several items simultaneously. To get around this limitation, Reckase and McKinley [20] developed item vector plots. In this approach, each item is represented by a vector that represents three characteristics: discrimination, difficulty, and location. Using orthogonal axes, *discrimination* corresponds to the length of the item response vector. This length represents the maximum amount of discrimination, and is referred to as MDISC. For item i , MDISC is given by

$$MDISC = \sqrt{a_{i1}^2 + a_{i2}^2}, \quad (6)$$

where a_1 and a_2 are the logistic model discrimination parameters. The tail of the vector lies on the $p = 0.5$ equiprobability contour. If extended, all vectors would pass through the origin of the latent trait plane. Further, the a -parameters are constrained to be positive, as with unidimensional IRT, and, thus, the item vectors will only be located in the first and third quadrants. MDISC is analogous to the a -parameter in unidimensional IRT.

Difficulty corresponds to the location of the vector in space. The signed distance from the origin to the $p = 0.5$ equiprobability contour, denoted by D , is given by Reckase [18] as

$$D = \frac{-d_i}{MDISC}, \quad (7)$$

where d_i is the difficulty parameter for item i . The sign of this distance indicates the relative difficulty of the item. Items with negative D are relatively easy, and are in the third quadrant, whereas items with positive D are relatively hard, and are in first quadrant. D is analogous to the b -parameter in unidimensional IRT.

Location corresponds to the angular direction of each item relative to the positive θ_1 axis. The location

of item i is given by

$$\alpha_i = \arccos \frac{a_{i1}}{MDISC_i}. \quad (8)$$

A vector with location α_i greater than 45 degrees is a better measure of θ_2 than θ_1 , whereas a vector with a location α_i less than 45 degrees is a better measure of θ_1 .

By examining the discrimination, difficulty, and location of each item response vector, the degree of similarity in the two-dimensional composite for all items on the test can be viewed. By color-coding items according to content, practitioners can understand better the different ability composites that are being assessed by their tests. In Figure 6 is a vector plot for 25 items from a mathematics usage test. Note that the composite angle 43.1° represents the average composite direction of the vectors weighted by each item's MDISC value. This direction indicates two-dimensional composite that would be estimated if this test were calibrated using a unidimensional model.

Information. In item response theory, measurement precision is evaluated using information. The reciprocal of the information function is the asymptotic variance of the maximum likelihood estimate of ability. This relationship implies that the larger the

Figure 6 A vector plot of 25 ACT mathematics usage items

information function, the smaller the asymptotic variance and the more measurement precision. Multidimensional information (MINF) serves as one measure of precision. MINF is computed in a manner similar to its unidimensional IRT counterpart, except that the direction of the information is also considered, as shown in the formula

$$MINF = P_i(\theta)[1 - P_i(\theta)] \left(\sum_{k=1}^m \alpha_{ik} \cos \alpha_{ik} \right)^2. \quad (9)$$

MINF provides a measure of information at any point on the latent ability plane (i.e., measurement precision relative to the θ_1, θ_2 composite). MINF can be computed at the item level or at the test level (where the test information is the sum of the item information functions).

Reckase and McKinley [20] developed a *clamshell* plot to represent information with MINF (the representation was said to resemble clamshells, hence the term). To create the clamshells, the amount of information is computed at 49 uniformly spaced points on a 7×7 grid in the θ_1, θ_2 space. At each of the 49 points, the amount of information is computed for 10 different directions or ability composites from 0 to 90 degrees in 10-degree increments, and represented as the length of the 10 lines in each clamshell. Figure 7 contains the clamshell plot for the 25 items

Figure 7 A clamshell information plot of 25 ACT mathematics usage items

whose vectors are displayed in Figure 6. At the ability (0,0), the clamshell vectors are almost of equal length, indicating that most of the composites tend to be measured with equal accuracy and much more accurately than would subjects located at the ability (3,3).

Ackerman [1] expanded upon the work of Reckase and McKinley and provided several other ways to graphically examine the information of two-dimensional tests. One example of his work was a number plot that was somewhat similar to the clamshell plot.

However, at each of the 49 points, the direction of maximum information is given as a numeric value on the grid, while the amount of information is represented by the size of the font for each numeric value (the larger the font, the greater the information). Figure 8 shows the number plot corresponding to the clamshell plot in Figure 7. Note that for examinees located at (0,0), the composite direction that is being best measured is at 40° . Such plots help to determine if two forms of a test are truly parallel.

Future Research Directions in MIRT

Multidimensional item response theory holds a great deal of promise for future psychometric research.

Figure 8 A number plot indicating the direction of maximum information at 49 ability locations

Directions in which MIRT research needs to be headed include computer adaptive testing [13], differential item functioning [22, 29], and diagnostic testing [7]. Other areas that need more development include expanding MIRT interpretations beyond two dimensions and to polytomous or Likert-type data [12, 17].

Multidimensional Scaling

Introduction

Multidimensional scaling is a statistical technique originating in psychometrics. The data used for multidimensional scaling (MDS) are dissimilarities between pairs of objects (*see Proximity Measures*). The main objective of MDS is to represent these dissimilarities as distances between points in a low dimensional space such that the distances correspond as closely as possible to the dissimilarities.

Let us introduce the method by means of a small example. Ekman [7] collected data to study the perception of 14 different colors. Every pair of colors was judged by a respondent from having ‘no similarity’ to being ‘identical’. The obtained scores can be scaled in such a way that identical colors are denoted by 0, and completely different colors by 1. The averages of these dissimilarity scores over the 31 respondents are presented in Table 1. Starting from wavelength 434, the colors range from bluish-purple, blue, green, yellow, to red. Note that the dissimilarities are symmetric: the extent to which colors with wavelengths 490 and 584 are the same is equal to that of colors 584 and 490. Therefore, it suffices to only present the lower triangular part of the data in Table 1. Also, the diagonal is not of interest in MDS because the distance of an object with itself is necessarily zero.

MDS tries to represent the dissimilarities in Table 1 in a map. Figure 1 presents such an MDS

map in 2 dimensions. We see that the colors, denoted by their wavelengths, are represented in the shape of a circle. The interpretation of this map should be done in terms of the depicted interpoint distances. Note that, as distances do not change under rotation, a rotation of the plot does not affect the interpretation. Similarly, a translation of the solution (that is, a shift of all coordinates by a fixed value per dimension) does not change the distances either, nor does a reflection of one or both of the axes.

Figure 1 should be interpreted as follows. Colors that are located close to each other are perceived as being similar. For example, the colors with wavelengths 434 (violet) and 445 (indigo) or 628 and 651 (both red). In contrast, colors that are positioned far away from each other, such as 490 (green) and 610 (orange) indicate a large difference in perception. The circular form obtained in this example is in accordance with theory on the perception of colors.

Summarizing, MDS is a technique that translates a table of dissimilarities between pairs of objects into a map where distances between the points match the dissimilarities as well as possible. The use of MDS is not limited to psychology but has applications in a wide area of disciplines, such as sociology, economics, biology, chemistry, and archaeology. Often, it is used as a technique for exploring the data. In addition, it can be used as a technique for dimension reduction. Sometimes, as in chemistry, the objective is to reconstruct a 3D model for large DNA-molecules for which only partial information of the distances between atoms is available.

Table 1 Dissimilarities of colors with wavelengths from 434 to 674 nm [7]

Data for MDS

In the previous section, we introduced MDS as a method to describe relationships between objects on the basis of observed dissimilarities. However, instead of dissimilarities we often observe similarities between objects. Correlations, for example, can be interpreted as similarities. By converting the similarities into dissimilarities MDS can easily be applied to similarity data. There are several ways of transforming similarities into dissimilarities. For example, we may take one divided by the similarity or we can apply any monotone decreasing function that yields nonnegative values (dissimilarities cannot be negative). However, in Section ‘Transformations of the Data’, we shall see that by applying transformations in MDS, there is no need to transform similarities into dissimilarities. To indicate both similarity and dissimilarity data, we use the generic term proximities.

Data in MDS can be obtained in a variety of ways. We distinguish between the direct collection of proximities versus derived proximities. The color data of the previous section is an example of direct proximities. That is, the data arrives in the format of proximities. Often, this is not the case and our data does not consist of proximities between variables. However, by considering an appropriate measure, proximities can be derived from the original data. For example, consider the case where objects are rated on several variables. If the interest lies in representing the variables, we can calculate the correlation matrix

as measure of similarity between the variables. MDS can be applied to describe the relationship between the variables on the basis of the derived proximities. Alternatively, if interest lies in the objects, Euclidean distances can be computed between the objects using the variables as dimensions. In this case, we use high dimensional Euclidean distances as dissimilarities and we can use MDS to reconstruct these distances in a low dimensional space.

Co-occurrence data are another source for obtaining dissimilarities. For such data, a respondent groups the objects into partitions and an $n \times n$ incidence matrix is derived where a one indicates that a pair of objects is in the same group and a zero indicates that they are in different groups. By considering the frequencies of objects being in the same or different groups and by applying special measures (such as the so-called *Jaccard similarity measure*), we obtain proximities. For a detailed discussion of various (dis)similarity measures, we refer to [8] (see **Proximity Measures**).

Formalizing Multidimensional Scaling

To formalize MDS, we need some notation. Let n be the number of different objects and let the dissimilarity for objects i and j be given by δ_{ij} . The coordinates are gathered in an $n \times p$ matrix $\mathbf{X}$, where p is the dimensionality of the solution to be specified in advance by the user. Thus, row i from $\mathbf{X}$ gives the

coordinates for object i . Let $d_{ij}(\mathbf{X})$ be the Euclidean distance between rows i and j of $\mathbf{X}$ defined as

$$d_{ij}(\mathbf{X}) = \left(\sum_{s=1}^p (x_{is} - x_{js})^2 \right)^{1/2}, \quad (1)$$

that is, the length of the shortest line connecting points i and j . The objective of MDS is to find a matrix $\mathbf{X}$ such that $d_{ij}(\mathbf{X})$ matches δ_{ij} as closely as possible. This objective can be formulated in a variety of ways but here we use the definition of raw Stress $\sigma^2(\mathbf{X})$, that is,

$$\sigma^2(\mathbf{X}) = \sum_{i=2}^n \sum_{j=1}^{i-1} w_{ij} (\delta_{ij} - d_{ij}(\mathbf{X}))^2 \quad (2)$$

by Kruskal [11, 12] who was the first one to propose a formal measure for doing MDS. This measure is also referred to as the least-squares MDS model. Note that due to the symmetry of the dissimilarities and the distances, the summation only involves the pairs ij where $i > j$. Here, w_{ij} is a user defined weight that must be nonnegative. For example, many MDS programs implicitly choose $w_{ij} = 0$ for dissimilarities that are missing.

The minimization of $\sigma^2(\mathbf{X})$ is a rather complex problem that cannot be solved in closed-form. Therefore, MDS programs use iterative numerical algorithms to find a matrix $\mathbf{X}$ for which $\sigma^2(\mathbf{X})$ is a minimum. One of the best algorithms available is the SMACOF algorithm [1, 3, 4, 5] based on iterative majorization. The SMACOF algorithm has been implemented in the SPSS procedure Proxscal [13]. In Section ‘The SMACOF Algorithm’, we give a brief illustration of the SMACOF algorithm.

Because Euclidean distances do not change under rotation, translation, and reflection, these operations may be freely applied to MDS solution without affecting the raw Stress. Many MDS programs use this indeterminacy to center the coordinates so that they sum to zero dimension wise. The freedom of rotation is often exploited to put the solution in so-called principal axis orientation. That is, the axes are rotated in such a way that the variance of $\mathbf{X}$ is maximal along the first dimension, the second dimension is uncorrelated to the first and has again maximal variance, and so on.

Here, we have discussed the Stress measure for MDS. However, there are several other measures for doing MDS. In Section ‘Alternative Measures for

Doing Multidimensional Scaling’, we briefly discuss other popular definitions of Stress.

Transformations of the Data

So far, we have assumed that the dissimilarities are known. However, this is often not the case. Consider for example the situation in which the objects have been ranked. That is, the dissimilarities between the objects are not known, but their order is known. In such a case, we would like to assign numerical values to the proximities in such a way that these values exhibit the same rank order as the data. These numerical values are usually called disparities, d-hats, or pseudo distances, and they are denoted by $\hat{d}$. The task of MDS now becomes to simultaneously obtain disparities and coordinates in such a way that the coordinates represent the disparities (and thus the original rank order of the data) as well as possible. This objective can be captured in minimizing a slight adaptation of raw Stress, that is,

$$\sigma^2(\hat{\mathbf{d}}, \mathbf{X}) = \sum_{i=2}^n \sum_{j=1}^{i-1} w_{ij} (\hat{d}_{ij} - d_{ij}(\mathbf{X}))^2, \quad (3)$$

over both the $\hat{\mathbf{d}}$ and $\mathbf{X}$, where $\hat{\mathbf{d}}$ is the vector containing $\hat{d}_{ij}$ for all pairs. The process of finding the disparities is called **optimal scaling** and was first introduced by Kruskal [11, 12]. Optimal scaling aims to find a transformation of the data that fits as well as possible the distances in the MDS solution. To avoid the trivial optimal scaling solution $\mathbf{X} = \mathbf{0}$ and $\hat{d}_{ij} = 0$ for all ij , we impose a length constraint on the disparities in such a way that the sum of squared d-hats equals a fixed constant. For example, $\sum_{i=2}^n \sum_{j=1}^{i-1} w_{ij} \hat{d}_{ij}^2 = n(n-1)/2$ [3].

Transformations of the data are often used in MDS. Figure 2 shows a few examples of transformation plots for the color example. Let us look at some special cases.

Suppose that we choose $\hat{d}_{ij} = \delta_{ij}$ for all ij . Then, minimizing (3) without the length constraint is exactly the same as minimizing (2). Minimizing (3) with the length constraint only changes $\hat{d}_{ij} = a\delta_{ij}$, where a is a scalar chosen in such a way that the length constraint is satisfied. This transformation is called a *ratio transformation* (Figure 2a). Note that, in this case, the relative differences of $a\delta_{ij}$ are the same as those for δ_{ij} . Hence, the relative differences

Figure 2 Four transformations often used in MDS

of the $d_{ij}(\mathbf{X})$ in (2) and (3) are also the same. Ratio MDS can be seen as the most restrictive transformation in MDS.

An obvious extension to the ratio transformation is obtained by allowing the $\hat{d}_{ij}$ to be a linear transformation of the δ_{ij} . That is, $\hat{d}_{ij} = a + b\delta_{ij}$, for some unknown values of a and b . Figure 2b depicts an interval transformation. This transformation may be chosen if there is reason to believe that $\delta_{ij} = 0$ does not have any particular interpretation. An interval transformation that is almost horizontal reveals little about the data as different dissimilarities are transformed to similar disparities. In such a case, the constant term will dominate the $\hat{d}_{ij}$'s. On the other hand, a good interval transformation is obtained if the line is not horizontal and the constant term is reasonably small with respect to the rest.

For ordinal MDS, the $\hat{d}_{ij}$ are only required to have the same rank order as δ_{ij} . That is, if for two pairs of objects ij and kl we have $\delta_{ij} \leq \delta_{kl}$ then the corresponding disparities must satisfy $\hat{d}_{ij} \leq \hat{d}_{kl}$.

An example of an ordinal transformation in MDS is given in Figure 2c. Typically, an ordinal transformation shows a step function. Similar to the case for interval transformations, it is not a good sign if the transformation plot shows a horizontal line. Moreover, if the transformation plot only exhibits a few steps, ordinal MDS does not use finer information available in the data. Ordinal MDS is particularly suited if the original data are rank orders. To compute an ordinal transformation a method called **monotone regression** can be used.

A monotone spline transformation offers more freedom than an interval transformation, but never more than an ordinal transformation (see **Scatterplot Smoothers**). The advantage of a spline transformation over an ordinal transformation is that it will yield a smooth transformation. Figure 2d shows an example of a spline transformation. A spline transformation is built on two ideas. First, the range of the δ_{ij} 's can be subdivided into connected intervals. Then, for each interval, the data are transformed

using a polynomial of a specified degree. For example, a second-degree polynomial imposes that $\hat{d}_{ij} = a\delta_{ij}^2 + b\delta_{ij} + c$. The special feature of a spline is that at the connections of the intervals, the so-called interior knots, the two polynomials connect smoothly. The spline transformation in Figure 2d was obtained by choosing one interior knot at .90 and by using second-degree polynomials. For MDS it is important that the transformation is monotone increasing. This requirement is automatically satisfied for monotone splines or I-Splines (see, [14, 1]). For choosing a transformation in MDS it suffices to know that a spline transformation is smooth and nonlinear. The amount of nonlinearity is governed by the number of interior knots specified. Unless the number of dissimilarities is very large, a few interior knots for a second-degree spline usually works well.

There are several reasons to use transformations in MDS. One reason concerns the fit of the data in low dimensionality. By choosing a transformation that is less restrictive than the ratio transformation a better fit may be obtained. Alternatively, there may exist theoretical reasons as to why a transformation of the dissimilarities is desired. Ordered from most to least restrictive transformation, we start with ratio, then interval, spline, and ordinal.

If the data are dissimilarities, then it is necessary that a transformation is monotone increasing (as in Figure 2) so that pairs with higher dissimilarities are indeed modeled by larger distances. Conversely, if the data are similarities, then the transformation should be monotone decreasing so that more similar pairs are

modeled by smaller distances. A ratio transformation is not possible for similarities. The reason is that the $\hat{d}_{ij}$'s must be nonnegative. This implies that the transformation must include an intercept.

In the MDS literature, one often encounters the terms metric and nonmetric MDS. Metric MDS refers to the ratio and interval transformations, whereas all other transformations such as ordinal and spline transformations are covered by the term nonmetric MDS. We believe, however, that it is better to refer directly to the type of transformation that is used.

There exist other a-priori transformations of the data that are not optimal in the sense described above. That is transformations that are not obtained by minimizing (3). The advantage of optimal transformations is that the exact form of the transformation is unknown and determined optimally together with the MDS configuration.

Diagnostics

In order to assess the quality of the MDS solution we can study the differences between the MDS solution and the data. One convenient way to do this is by inspecting the so-called **Shepard diagram**.

A Shepard diagram shows both the transformation and the error. Let p_{ij} denotes the proximity between objects i and j . Then, a Shepard diagram plots simultaneously the pairs $(p_{ij}, d_{ij}(\mathbf{X}))$ and $(p_{ij}, \hat{d}_{ij})$. In Figure 3, solid points denote the pairs $(p_{ij}, d_{ij}(\mathbf{X}))$ and open circles represent the pairs $(p_{ij}, \hat{d}_{ij})$. By

Figure 3 Shepard diagram for ordinal MDS of the color data, where the proximities are dissimilarities

Figure 4 Shepard diagram for ordinal MDS of the color data, where the proximities are dissimilarities

connecting the open circles a line is obtained representing the relationship between the proximities and the disparities which is equivalent to the transformation plots in Figure 2. The vertical distances between the open and closed circles are equal to $\hat{d}_{ij} - d_{ij}(\mathbf{X})$, that is, they give the errors of representation for each pair of objects. Hence, the Shepard diagram can be used to inspect both the residuals of the MDS solution and the transformation. Outliers can be detected as well as possible systematic deviations. Figure 3 gives the Shepard diagram for the ratio MDS solution of Figure 1 using the color data. We see that all the errors corresponding to low proximities are positive whereas the errors for the higher proximities are all negative. This kind of heteroscedasticity suggests the use of a more liberal transformation. Figure 4 gives the Shepard diagram for an ordinal transformation. As the solid points are closer to the line connecting the open circles, we may indeed conclude that the heteroscedasticity has gone and that the fit has become better.

Choosing the Dimensionality

Several methods have been proposed to choose the dimensionality of the MDS solution. However, no definite strategy is present. **Unidimensional scaling**, that is, $p = 1$ (with ratio transformation) has to be treated with special care because the usual MDS algorithms will end up in local minima that can be far from global minima.

One approach to determine the dimensionality is to compute MDS solutions for a range of dimensions, say from 2 to 6 dimensions, and plot the Stress against the dimension. Similar to common practice in principal component analysis, we then use the elbow criterion to determine the dimensionality. That is, we choose the number of dimensions where a bend in the curve occurs.

Another approach (for ordinal MDS), proposed by [15], compares the Stress values against the Stress of generated data. However, perhaps the most important criterion for choosing the dimensionality is simply based on the interpretability of the map. Therefore, the vast majority of reported MDS solutions are done in two dimensions and occasionally in three dimensions. The interpretability criterion is a valid one especially when MDS is used for exploration of the data.

The SMACOF Algorithm

In Section ‘Formalizing Multidimensional Scaling’, we mentioned that a popular algorithm for minimizing Stress is the SMACOF Algorithm. Its major feature is that it guarantees lower Stress values in each iteration. Here we briefly sketch how this algorithm works.

Nowadays, the acronym SMACOF stands for Scaling by Majorizing a Complex Function. To understand how it works, consider Figure 5a. Suppose that we have dissimilarity data on 13 stock

Figure 5 The Stress function and the majorizing function for the supporting (0,0) in Panel a., and the majorizing function at convergence in Panel b. Reproduced by permission of Vrieseborch Publishers

markets and that the two dimensional MDS solution is given by the points in the horizontal plane of Figure 5a and 5b. Now, suppose that the position of the 'nikkei' index was unknown. Then we can calculate the value of Stress as a function of the two coordinates for 'nikkei'. The surface in Figure 5a shows these values of Stress for every potential position of 'nikkei'. To minimize Stress we must find the coordinates that yield the lowest Stress. Hence, the final point must be located in the horizontal plane under the lowest value of the surface. To find this point, we use an iterative procedure that is based on majorization. First, as an initial point for 'nikkei' we choose the origin in Figure 5a. Then, a so-called majorization function is chosen in such a way that, for this initial point, its value is equal to the Stress value, and elsewhere it lies above the Stress surface. Here, the majorizing function is chosen to be quadratic and is visualized in Figure 5a as the bowl-shaped surface above the Stress function surface. Now, as the Stress surface is always below the majorization function, the value of Stress evaluated at the point corresponding to the minimum of the majorization function, will be lower than the initial Stress value. Hence, the initial point can be updated by calculating the minimum of the majorization function which is easy because the majorizing function is quadratic. Using the updated point we repeat this process until the coordinates remain practically

constant. Figure 5b shows the subsequent coordinates for 'nikkei' obtained by majorization as a line with connected dots marking the path to its final position.

Alternative Measures for Doing Multidimensional Scaling

In addition to the raw Stress measure introduced in Section 'Formalizing Multidimensional Scaling', there exist other measures for doing Stress. Here we give a short overview of some of the most popular alternatives. First, we discuss normalized raw Stress,

$$\sigma_n^2(\hat{\mathbf{d}}, \mathbf{X}) = \frac{\sum_{i=2}^n \sum_{j=1}^{i-1} w_{ij} (\hat{d}_{ij} - d_{ij}(\mathbf{X}))^2}{\sum_{i=2}^n \sum_{j=1}^{i-1} w_{ij} \hat{d}_{ij}^2}, \quad (4)$$

which is simply raw Stress divided by the sum of squared dissimilarities. The advantage of this measure over raw Stress is that its value is independent of the scale of the dissimilarities and their number. Thus, multiplying the dissimilarities by a positive factor will not change (4) at a local minimum, whereas the coordinates will be the same up to the same factor.

The second measure is Kruskal's Stress-1 formula

$$\sigma_1(\hat{\mathbf{d}}, \mathbf{X}) = \left(\frac{\sum_{i=2}^n \sum_{j=1}^{i-1} w_{ij} (\hat{d}_{ij} - d_{ij}(\mathbf{X}))^2}{\sum_{i=2}^n \sum_{j=1}^{i-1} w_{ij} d_{ij}^2(\mathbf{X})} \right)^{1/2}, \quad (5)$$

which is equal to the square root of raw Stress divided by the sum of squared distances. This measure is of importance because many MDS programs and publications report this value. It can be proved that at a local minimum of $\sigma_n^2(\hat{\mathbf{d}}, \mathbf{X})$, $\sigma_1(\hat{\mathbf{d}}, \mathbf{X})$ also has a local minimum with the same configuration up to a multiplicative constant. In addition, the square root of normalized raw Stress is equal to Stress-1 [1].

A third measure is Kruskal's Stress-2, which is similar to Stress-1 except that the denominator is based on the variance of the distances instead of the sum of squares. Stress-2 can be used to avoid the situation where all distances are almost equal.

A final measure that seems reasonably popular is called *S-Stress* (implemented in the program ALSCAL) and it measures the sum of squared error between *squared* distances and *squared* dissimilarities [16]. The disadvantage of this measure is that it tends to give solutions in which large dissimilarities are overemphasized and the small dissimilarities are not well represented.

Pitfalls

If missing dissimilarities are present, a special problem may occur for certain patterns of missing dissimilarities. For example, if it is possible to split the objects in two or more sets such that the between-set

weights w_{ij} are all zero, we are dealing with independent MDS problems, one for each set. If this situation is not recognized, you may inadvertently interpret the missing between set distances. With only a few missing values, this situation is unlikely to happen. However, when dealing with many missing values, one should verify that the problem does not occur.

Another important issue is to understand what MDS will do if there is no information in the data, that is, when all dissimilarities are equal. Such a case can be seen as maximally uninformative and therefore as a null model. Solutions of empirical data should deviate from this null model. This situation was studied in great detail by [2]. It turned out that for constant dissimilarities, MDS will find in one dimension points equally spread on a line (see Figure 6). In two dimensions, the points lie on concentric circles [6] and in three dimensions (or higher), the points lie equally spaced on the surface of a sphere. Because all dissimilarities are equal, any permutation of these points yield an equally good fit.

This type of degeneracy can be easily recognized by checking the Shepard diagram. For example, if all disparities (or dissimilarities in ratio MDS) fall into a small interval considerably different from zero, we are dealing with the case of (almost) constant dissimilarities. For such a case, we advise redoing the MDS analysis with a more restrictive transformation, for example, using monotone splines, an interval transformation or even ratio MDS.

A final pitfall for MDS are local minima. A local minimum for Stress implies that small changes in the configuration always have a worse Stress than the local minimum solution. However, larger changes in the configuration may yield a lower Stress. A configuration with the overall lowest Stress value is called a *global minimum*. In general, MDS algorithms that minimize Stress cannot guarantee the retrieval of

Figure 6 Solutions for constant dissimilarities with $n = 30$. The left plot shows the unidimensional solution and the right plot a 2D solution

a global minimum. However, if the dimensionality is exactly $n - 1$, it is known that ratio MDS only has one minimum that is consequently global. Moreover, when $p = n - 1$ is specified, MDS often yields a solution that fits in a dimensionality lower than $n - 1$. If so, then this MDS solution is also a global minimum. A different case is that of unidimensional scaling. For unidimensional scaling with a ratio transformation, it is well known that it has many local minima and can better be solved using combinatorial methods. For low dimensionality, like $p = 2$ or $p = 3$, experiments indicated that the number of different local minima ranges from a few to several thousands. For an overview of issues concerning local minima in ratio MDS, we refer to [9] and [10].

When transformations are used, there are fewer local minima and the probability of finding a global minimum increases. As a general strategy, we advice to use multiple random starts (say 100 random starts) and retain the solution with the lowest Stress. If most random starts end in the same candidate minimum, then there probably only exist few local minima. However, if the random starts end in many different local minima, the data exhibit a serious local minimum problem. In that case, it is advisable to increase the number of random starts and retain the best solution.

Multidimensional Unfolding

The unfolding model is a geometric model for preference and choice. It locates individuals and alternatives as points in a joint space, and it says that an individual will pick the alternative in the choice set closest to its ideal point. Unfolding originated in the work of Coombs [4] and his students. It is perhaps the dominant model in both **scaling of preference data** and **attitude scaling**.

The multidimensional unfolding technique computes solutions to the equations of unfolding model. It can be defined as **multidimensional scaling** of off-diagonal matrices. This means the data are dissimilarities between n row objects and m column objects, collected in an $n \times m$ matrix Δ . An important example is preference data, where δ_{ij} indicates, for instance, how much individual i dislikes object j . In unfolding, we have many of the same distinctions as in general multidimensional scaling: there is uni-dimensional and multidimensional unfolding, metric and nonmetric unfolding, and there are many possible choices of loss functions that can be minimized.

First we will look at (metric) unfolding as defining the system of equations $\delta_{ij} = d_{ij}(X, Y)$, where X is the $n \times p$ configuration matrix of row points, Y is the $m \times p$ configuration matrix of column points, and

$$d_{ij}(X, Y) = \sqrt{\sum_{s=1}^p (x_{is} - y_{js})^2}. \quad (1)$$

Clearly, an equivalent system of algebraic equations is $\delta_{ij}^2 = d_{ij}^2(X, Y)$, and this system expands to

$$\delta_{ij}^2 = \sum_{s=1}^p x_{is}^2 + \sum_{s=1}^p y_{js}^2 - 2 \sum_{s=1}^p x_{is} y_{js}. \quad (2)$$

We can rewrite this in matrix form as $\Delta^{(2)} = ae'_m + e_n b' - 2XY'$, where a and b contain the row and column sums of squares, and where e is used for a vector with all elements equal to one. If we define the centering operators $J_n = I_n - e_n e'_n / n$ and $J_m = I_m - e_m e'_m / m$, then we see that doubly centering the matrix of squared dissimilarities gives the basic result

$$H = -\frac{1}{2} J_n \Delta^{(2)} J_m = \tilde{X} \tilde{Y}', \quad (3)$$

where $\tilde{X} = J_n X$ and $\tilde{Y} = J_m Y$ are centered versions of X and Y . For our system of equations to be solvable, it is necessary that $\text{rank}(H) \leq p$. Solving the system, or finding an approximate solution by using the singular value decomposition, gives us already an idea about X and Y , except that we do not know the relative location and orientation of the two point-clouds.

More precisely, if $H = PQ'$ is full rank decomposition of H , then the solutions X and Y of our system of equations $\delta_{ij}^2 = d_{ij}^2(X, Y)$ can be written in the form

$$\begin{aligned} X &= (P + e_n \alpha') T, \\ Y &= (Q + e_m \beta') (T')^{-1}, \end{aligned} \quad (4)$$

which leaves us with only the $p(p+2)$ unknowns in α , β , and T still to be determined. By using the fact that the solution is invariant under translation and rotation, we can actually reduce this to $(1/2)p(p+3)$ parameters. One way to find these additional parameters is given in [10].

Instead of trying to find an exact solution, if one actually exists, by algebraic means, we can also define a multidimensional unfolding loss function and minimize it. In the most basic and classical form, we have the Stress loss function

$$\sigma(X, Y) = \sum_{i=1}^n \sum_{j=1}^m w_{ij} (\delta_{ij} - d_{ij}(X, Y))^2. \quad (5)$$

This is identical to an ordinary multidimensional scaling problem in which the diagonal (row–row and column–column) weights are zero. Or, to put it differently, in unfolding, the dissimilarities between different row objects and different column objects are missing. Thus, any multidimensional scaling program that can handle weights and missing data can be used to minimize this loss function. Details are in [7] or [1, Part III]. One can also consider measuring loss using SStress, the sum of squared differences between the squared dissimilarities and squared distances. This has been considered in [6, 11].

We use an example from [9, p. 152]. The Department of Psychology at the University of Nijmegen has, or had, nine different areas of research and teaching. Each of the 39 psychologists working in the department ranked all nine areas in order of relevance for their work. The areas are given in Table 1.

2 Multidimensional Unfolding

Figure 1 Metric Unfolding Roskam Data

We apply metric unfolding, in two dimensions, and find the solution in Figure 1.

In this analysis, we used the rank orders, more precisely the numbers 0 to 8. Thus, for good fit, first choices should coincide with ideal points. The grouping of the nine areas in the solution is quite natural and shows the contrast between the more scientific and the more humanistic and clinical areas.

Table 1 Nine psychology areas

Area	Plot code
Social Psychology	SOC
Educational and Developmental Psychology	EDU
Clinical Psychology	CLI
Mathematical Psychology and Psychological Statistics	MAT
Experimental Psychology	EXP
Cultural Psychology and Psychology of Religion	CUL
Industrial Psychology	IND
Test Construction and Validation	TST
Physiological and Animal Psychology	PHY

In this case, and in many other cases, the problems we are analyzing suggest that we really are interested in nonmetric unfolding. It is difficult to think of actual applications of metric unfolding, except perhaps in the life and physical sciences. This does not mean that metric unfolding is uninteresting. Most nonmetric unfolding algorithms solve metric unfolding subproblems, and one can often make a case for metric unfolding as a robust form to solve nonmetric unfolding problems.

The original techniques proposed by Coombs [4] were purely nonmetric and did not even lead to metric representations. In preference analysis, the prototypical area of application, we often only have ranking information. Each individual ranks a number of candidates, or food samples, or investment opportunities. The ranking information is row-conditional, which means we cannot compare the ranks given by individual i to the ranks given by individual k . The order is defined only within rows. Metric data are generally unconditional, because we can compare numbers both within and between rows. Because of the paucity of information (only rank order, only row-conditional, only off-diagonal), the usual Kruskal approach to

Figure 2 Nonmetric unfolding Roskam data

nonmetric unfolding often leads to degenerate solutions, even after clever renormalization and partitioning of the loss function [8]. In Figure 2, we give the solution minimizing

$$\sigma(X, Y, \Delta) = \sum_{i=1}^n \frac{\sum_{j=1}^m w_{ij}(\delta_{ij} - d_{ij}(X, Y))^2}{\sum_{j=1}^m w_{ij}(\delta_{ij} - \delta_{i*})^2} \quad (6)$$

over X and Y and over those Δ whose rows are monotone with the ranks given by the psychologists. Thus, there is a separate **monotone regression** computed for each of the 39 rows.

The solution is roughly the same as the metric one, but there is more clustering and clumping in the plot, and this makes the visual representation much less clear. It is quite possible that continuing to iterate to higher precision will lead to even more degeneracy. More recently, Busing et al. [2] have adapted the Kruskal approach to nonmetric unfolding by penalizing for the flatness of the monotone regression function.

One would expect even more problems when the data are not even rank orders but just binary choices. Suppose n individuals have to choose one alternative

from a set of m alternatives. The data can be coded as an *indicator matrix*, which is an $n \times m$ binary matrix with exactly one unit element in each row. The unfolding model says there are n points x_i and m points y_j in $\mathbb{R}^p$ such that if individual i picks alternative j , then $\|x_i - y_j\| \leq \|x_i - y_\ell\|$ for all $\ell = 1, \dots, m$. More concisely, we use the m points y_j to draw a *Voronoi diagram*. This is illustrated in Figure 3 for six points in the plane.

There is one Voronoi cell for each y_j , and the cell (which can be bounded or unbounded) contains exactly those points that are closer to y_j than to any of the other y_ℓ 's. The unfolding model says that individuals are in the Voronoi cells of the objects they pick. This clearly leaves room for a lot of indeterminacy in the actual placement of the points.

The situation becomes more favorable if we have more than one indicator matrix, that is, if each individual makes more than one choice. There is a Voronoi diagram for each choice and individuals must be in the Voronoi cells of the object they choose for each of the diagrams. Superimposing the diagrams creates smaller and smaller regions that each individual must be in, and the unfolding model requires the intersection of the Voronoi cells determined by the choices of any individual to be nonempty.

4 Multidimensional Unfolding

Figure 3 A Voronoi diagram

Figure 4 Unfolding binary data

It is perhaps simplest to apply this idea to binary choices. The Voronoi cells in this case are half spaces defined by hyperplanes dividing $\mathbb{R}^n$ in two parts. All individuals choosing the first of the two alternatives must be on one side of the hyperplane, all others must be on the other side. There is a hyperplane for each choice.

This is the nonmetric factor analysis model studied first by [5]. It is illustrated in Figure 4.

The prototype here is roll call data [3]. If 100 US senators vote on 20 issues, then the unfolding model says that (for a representation in the plane) there are 100 points and 20 lines, such that each issue-line separates the 'aye' and the 'nay' voters for

Figure 5 The 2000 US senate

that issue. Unfolding, in this case, can be done by **correspondence analysis**, or by maximum likelihood logit or probit techniques. We give an example, using 20 issues selected by Americans for Democratic Action, the 2000 US Senate, and the logit technique (Figure 5).

The issue lines are the perpendicular bisectors of the lines connecting the 'aye' and 'nay' points of the issues. We see for the figure how polarized American politics is, with almost all lines going through the center and separating Democrats from Republicans.

Multigraph Modeling

13 ————— 23

Multigraph modeling is a graphical technique used to (1) identify whether a hierarchical **loglinear model** (HLM) is decomposable or not, (2) obtain an explicit factorization of joint probabilities in terms of marginal probabilities for decomposable HLMs, and (3) interpret the conditional independence structure (see **Probability: An Introduction**) of a given HLM of a **contingency table**. Consider a multiway contingency table and a corresponding HLM (see e.g., [1–3], or [11]). The HLM is uniquely characterized by its *generating class* (or *minimal sufficient configuration*), which establishes the correspondence between the model parameters and the associated minimal sufficient statistics. As an example, consider the model of conditional independence for a three-way contingency table (using Agresti’s [1] notation):

$$\log m_{ijk} = \mu + \lambda_i^1 + \lambda_j^2 + \lambda_k^3 + \lambda_{ik}^{13} + \lambda_{jk}^{23}, \quad (1)$$

where m_{ijk} denotes the expected cell frequency for the i th row, j th column, and k th layer of the contingency table, and the parameters on the right side of the equation represent certain contrasts of $\log m_{ijk}$. The generating class for this model is denoted by [13][23]; it corresponds to the inclusion-maximal sets of indices in the model, $\{1, 3\}$ and $\{2, 3\}$, referred to as the *generators* of the model. This model represents conditional independence of factors 1 and 2 given factor 3, written as $[1 \otimes 2]3$.

A *graph* G is a mathematical object that consists of two sets: (1) a set of *vertices*, V , and (2) a set of *edges*, E , consisting of pairs of elements taken from V . The diagram of the graph is a picture in which a circle or dot or some other symbol represents a vertex and a line represents an edge. The *generator multigraph*, or simply *multigraph*, M of an HLM is a graph in which the vertex set consists of the set of generators of the HLM, and two vertices are joined by edges that are equal in number to the number of indices shared by them. The multigraph for the model in (1) is given in Figure 1. The vertices of this multigraph consist of the two generators of the model $\{1, 3\}$ and $\{2, 3\}$, and there is a single edge joining the two vertices because $\{1, 3\} \cap \{2, 3\} = \{3\}$. Note the one-to-one correspondence between the generating class and the multigraph representation.

Figure 1 Generator multigraph for the loglinear model [13] [23]

A *maximum spanning tree* T of a multigraph is a connected graph with no circuits (or closed loops) that includes each vertex of the multigraph such that the sum of all of the edges is maximum. Each maximum spanning tree consists of a family of sets of factor indices called the *branches* of the tree. For the multigraph in Figure 1, the maximum spanning tree is the edge (branch) joining the two vertices and is denoted by $T = \{3\}$.

An *edge cutset* of a multigraph is an inclusion-minimal set of multiedges whose removal disconnects the multigraph. For the model [13][23] with the multigraph given in Figure 1, there is a single-edge cutset that disconnects the two vertices, $\{3\}$, and it is the minimum number of edges that does so. General results concerning the multigraph are given as follows:

An HLM is *decomposable* if and only if [10]

$$d = \sum_{S \in V(T)} |S| - \sum_{S \in B(T)} |S|, \quad (2)$$

where d = number of factors in the contingency table, T is any maximum spanning tree of the multigraph, $V(T)$ and $B(T)$ are the set of vertices and set of branches of T respectively, and $S \in V(T)$ and $S \in B(T)$ represent the factor indices contained in $V(T)$ and $B(T)$ respectively.

For decomposable models, the joint distribution for the associated contingency table is [10]:

$$P[v_1, v_2, \dots, v_d] = \frac{\prod_{S \in V(T)} P[v : V \in S]}{\prod_{S \in B(T)} P[v : V \in S]}, \quad (3)$$

where $P[v_1, v_2, \dots, v_d]$ represents the probability associated with level v_1 of the first factor, level v_2 of the second factor, and so on, and level v_d of the d th factor. $P[v : V \in S]$ denotes the marginal probability indexed on those indices contained in S (and summing over all other indices). From this factorization, an explicit formula for the maximum likelihood estimator (see **Maximum Likelihood Estimation**) can be obtained (see, e.g., [2]).

2 Multigraph Modeling

In order to identify the conditional independence structure of a given HLM, the branches and edge cutsets of the multigraph are used. For a given multigraph M and set of factors S , construct the multigraph M/S by removing each factor of S from each generator (vertex in the multigraph) and removing each edge corresponding to that factor. For decomposable models, S is chosen to be a branch of any maximum spanning tree of M , and for nondecomposable models, S is chosen to be the factors corresponding to an edge cutset of M . Then, the conditional independence interpretation for the HLM is the following: The sets of factors in the disconnected components of M/S are mutually independent, conditional on S [10].

For the multigraph in Figure 1, $d = 3$, $T = \{3\}$, $V(T) = \{\{1, 3\}, \{2, 3\}\}$, and $B(T) = \{3\}$. By (2), $3 = (2 + 2) - 1$ so that the HLM [13][23] is decomposable, and by (3), the factorization of the joint distribution is (using simpler notation) $p_{ijk} = p_{i+k}p_{+jk}/p_{++k}$. Upon removing $S = \{3\}$ from the multigraph, the sets of factors in the disconnected components of M/S are $\{1\}$ and $\{2\}$. Hence, the interpretation of [13][23] is $[1 \otimes 2|3]$.

Edwards and Kreiner [6] analyzed a set of data in the form of a five-way contingency table from an investigation conducted at the Institute for Social Research, Copenhagen. A sample of 1592 employed men, 18 to 67 years old, were asked whether in the preceding year they had done any work they would have previously paid a craftsman to do. The variables included in the study are shown in Table 1.

One of the HLMs that fits the data well is $[AME][RME][AMT]$. The multigraph for this model is given in Figure 2. The maximum spanning tree for this multigraph is $T = \{\{M, E\}, \{A, M\}\}$, where $V(T) = \{\{A, M, E\}, \{R, M, E\}, \{A, M, T\}\}$ and $B(T) = \{\{M, E\}, \{A, M\}\}$. From (2), $5 = (3 + 3 + 3) - (2 + 2)$, indicating that $[AME][RME][AMT]$ is a decomposable model, and the factorization of the

Figure 2 Generator multigraph for the loglinear model $[AME][RME][AMT]$

Figure 3 Multigraphs M/S and conditional independence interpretations for the loglinear model $[AME][RME][AMT]$ with branches: (a) $S = \{M, E\}$ and (b) $S = \{A, M\}$

joint probability can be obtained directly from (3). The multigraph M/S that results from choosing the branch $S = \{M, E\}$ is shown in Figure 3(a). The resulting interpretation is $[A, T \otimes R | M, E]$. Analogously, for $S = \{A, M\}$, we have $[R, E \otimes T | A, M]$ (Figure 3b).

The multigraph is typically smaller (i.e., has fewer vertices) than the first-order interaction graph introduced by Darroch et al. [4] (see also [5], [8], and [9]), especially for contingency tables with many factors and few generators. For the theoretical development of multigraph modeling, see [10]. For a further description of the application of multigraph modeling and additional examples, see [7].

Multilevel and SEM Approaches to Growth Curve Modeling

Introduction

A broad range of statistical methods exists for analyzing data from longitudinal designs (*see Longitudinal Data Analysis*). Each of these methods has specific features and the use of a particular method in a specific situation depends on such things as the type of research, the research question, and so on. The central concern of longitudinal research, however, revolves around the description of patterns of stability and change, and the explanation of how and why change does or does not take place [9].

A common design for longitudinal research in the social sciences is the panel or repeated measures design (*see Repeated Measures Analysis of Variance*), in which a sample of subjects is observed at more than one point in time. If all individuals provide measurements at the same set of occasions, we have a fixed occasions design. When occasions are varying, we have a set of measures taken at different points in time for different individuals. Such data occur, for instance, in growth studies, where individual measurements are collected for a sample of individuals at different occasions in their development (*see Growth Curve Modeling*). The data collection could be at fixed occasions, but the individuals have different ages. The distinction between fixed occasions designs and varying occasions designs is important, since they may lead to different analysis methods.

Several distinct statistical techniques are available for the analyses of panel data. In recent years, growth curve modeling has become popular [11, 12, 13, 24]. All subjects in a given population are assumed to have developmental curves of the same functional form (e.g., all linear), but the parameters describing their curves may differ. With linear developmental curves, for example, there may be individual differences in the initial level as well as in the growth rate or rate of change. Growth curve analysis is a statistical technique to estimate these parameters. Growth curve analysis is used to obtain a description of the mean growth in a population over a specific period of time (*see Growth Curve Modeling*). However, the

main emphasis lies in explaining variability between subjects in the parameters that describe their growth curves, that is, in interindividual differences in intra-individual change [25].

The model on which growth curve analysis is based, the growth curve model, can be approached from several perspectives. On the one hand, the model can be constructed as a standard two-level multilevel regression (MLR) model [4, 5, 20] (*see Linear Multilevel Models*). The repeated measures are positioned at the lowest level (level-1 or the occasion level), and are then treated as nested within the individuals (level-2 or the individual level), the same way as a standard cross-sectional multilevel model treats children as being nested within classes. The model can therefore be estimated using standard MLR software. On the other hand, the model can be constructed as a **structural equation model (SEM)**. Structural equation modeling uses latent variables to account for the relations between the observed variables, hence the name *latent growth curve (LGC)* model. The two approaches can be used to formulate equivalent models, providing identical estimates for a given data set [3].

The Longitudinal Multilevel or Latent Growth Curve Model

Both MLR and LGC incorporate the factor ‘time’ explicitly. Within the MLR framework time is modeled as an independent variable at the lowest level, the individual is defined at the second level, and explanatory variables can be included at all existing levels. The intercept and slope describe the mean growth. Interindividual differences in the parameters describing the growth curve are modeled as random effects for the intercept and slope of the time variable. The LGC approach adopts a latent variable view. Time is incorporated as specific constrained values for the factor loadings of the latent variable that represents the slope of the growth curve; all factor loadings of the latent variable that represents the intercept are constrained to the value of 1. The latent variable means for the intercept and slope factor describe the mean growth. Interindividual differences in the parameters describing the growth curve are modeled as the (co)variances of the intercept and slope factors. The mean and covariance structure of the latent variables in LGC analysis correspond to the fixed and

2 Multilevel and SEM Approaches to Growth Curve Modeling

random effects in MLR analysis, and this makes it possible to specify exactly the same model as a LGC or MLR model [23]. If this is done, exactly the same parameter estimates will emerge, as will be illustrated in the example.

The general growth curve model, for the repeatedly measured variable y_{ti} of individual i at occasion t , may be written as:

$$\begin{aligned} y_{ti} &= \lambda_{0t}\eta_{0i} + \lambda_{1t}\eta_{1i} + \gamma_{2t}x_{ti} + \varepsilon_{ti} \\ \eta_{0i} &= \nu_0 + \gamma_0z_i + \zeta_{0i} \\ \eta_{1i} &= \nu_1 + \gamma_1z_i + \zeta_{1i}, \end{aligned} \quad (1)$$

where λ_{1t} denotes the time of measurement and λ_{0t} a constant equal to the value of 1. Note that in a fixed occasions design λ_{1t} will typically be a consecutive series of integers (e.g., $[0, 1, 2, \dots, T]$) equal to all individuals, while in a varying occasions design λ_{1t} can take on different values across individuals. The individual intercept and slope of the growth curve are represented by η_{0i} and η_{1i} , respectively, with expectations ν_0 and ν_1 , and random departures or residuals, ζ_{0i} and ζ_{1i} , respectively. γ_{2t} represents the effect of the time-varying covariate x_{ti} ; γ_0 and γ_1 are the effects of the time-invariant covariate on the initial level and linear slope. Time-specific deviations are represented by the independent and identically standard normal distributed ε_{ti} , with variance σ_ε^2 . The variances of ζ_{0i} and ζ_{1i} , and their covariance are represented by:

$$\Sigma_\zeta = \begin{bmatrix} \sigma_0^2 & \\ \sigma_{01} & \sigma_1^2 \end{bmatrix}. \quad (2)$$

Furthermore, it is assumed that $\text{cov}(\varepsilon_{it}, \varepsilon_{it'}) = 0$, $\text{cov}(\varepsilon_{it}, \eta_{i0}) = 0$, $\text{cov}(\varepsilon_{it}, \eta_{i1}) = 0$.

Within the longitudinal MLR model η_{0i} and η_{1i} are the random parameters, and λ_{1t} is an observed variable representing time. In the LGC model η_{0i} and η_{1i} are the latent variables and λ_{0t} and λ_{1t} are parameters, that is, factor loadings. Thus, the only difference between the models is the way time is incorporated in the model. In the MLR model time is introduced as a fixed explanatory variable, whereas in the LGC model it is introduced via the factor loadings. So, in the longitudinal MLR model an additional variable is added, and in the LGC model the factor loadings for the repeatedly measured variable are constrained in such a way that they represent time. The consequence of this is that with reference to the basic

growth curve model, MLR is essentially a univariate approach, with time points treated as observations of the same variable, whereas the LGC model is essentially a multivariate approach, with each time point treated as a separate variable [23]. Figure 1 presents a path diagram depicting a LGC model for four measurement occasions, for simplicity without covariates. Following SEM conventions, the first path for the latent slope factor, which is constrained to equal zero, is usually not present in the diagram.

The specific ways MLR and LGC model ‘time’ have certain consequences for the analysis. In the LGC approach, λ_{1t} cannot vary between subjects, which makes it best suited for a fixed occasions design. LGC modeling can be used for designs with varying occasions by modeling all existing occasions and viewing the varying occasions as a missing data problem, but when the number of existing cases is large this approach becomes unmanageable. In the MLR approach, λ_{1t} is simply a time-varying explanatory variable that can take on any variable, which makes MLR the best approach if there are a large number of varying occasions. There are also some differences between the LGC and MLR approach in the ways the model can be extended. In the LGC approach, it is straightforward to embed the LGC model in a larger path model, for instance, by combining several growth curves in one model, or by using the intercept and slope factors as predictors for outcome values measured at a later occasion. The MLR approach does not deal well with such extended models. On the other hand, in the MLR approach it is simple to add more levels, for instance to model a growth process of pupils nested in classes nested in schools. In the LGC approach, it is possible to embed a LGC model in a two-level structural equation model [14], but adding more levels is problematic.

Example

We will illustrate the application of both the MLR model and the LGC model using a hypothetical study in which data on the language acquisition of 300 children were collected during primary school at 4 consecutive occasions. Besides this, data were collected on the children’s intelligence, as well as, on each occasion a measure of their emotional well-being. The same data have been analyzed by Stoel, et al. [23], who also discuss extensions and applications of both models.

Figure 1 Path diagram of a four-wave latent growth curve model

The aim of the study is testing the hypothesis that there exists substantial growth in language acquisition, and that there is substantial variability between the children in their growth curves. Given interindividual differences in the growth curves, it is hypothesized that intelligence explains (part of) the interindividual variation in the growth

curves and that emotional well-being explains the time-specific deviations from the mean growth curve. The covariance matrix and mean vector are presented in Table 1.

Analyzing these data using both the MLR and LGC model with Maximum Likelihood estimation leads to the parameter estimates presented in Table 2.

Table 1 Covariance matrix and means vector

	y ₁	y ₂	y ₃	y ₄	x ₁	x ₂	x ₃	x ₄	z	means
y ₁	1.58									9.83
y ₂	1.28	4.15								11.72
y ₃	1.52	4.91	8.90							13.66
y ₄	1.77	6.83	11.26	17.50						15.65
x ₁	0.99	-0.08	-0.26	-0.33	2.17					0.00
x ₂	0.16	1.44	0.17	0.18	0.13	2.56				0.00
x ₃	0.07	-0.13	1.2	-0.27	-0.06	-0.09	2.35			0.00
x ₄	0.08	0.23	0.46	1.98	0.03	-0.04	0.10	2.24		0.00
z	0.34	1.28	2.01	3.01	-0.08	0.07	0.01	0.06	0.96	0.00

Note: y = language acquisition, x = emotional well-being, z = intelligence.

4 Multilevel and SEM Approaches to Growth Curve Modeling

Table 2 Maximum likelihood estimates of the parameters of (1), using multilevel regression and latent growth curve analysis

Parameter	MLR	LGC
<i>Fixed part</i>		
ν_0	9.89 (.06)	9.89 (.06)
ν_1	1.96 (.05)	1.96 (.05)
γ_0	0.40 (.06)	0.40 (.06)
γ_1	0.90 (.05)	0.90 (.05)
γ_2	0.55 (.01)	0.55 (.01)
<i>Random part</i>		
σ_ϵ^2	0.25 (.01)	0.25 (.01)
σ_0^2	0.78 (.08)	0.78 (.08)
σ_1^2	0.64 (.06)	0.64 (.06)
σ_{01}	0.00 (.05)	0.00 (.05)

Note: Standard errors are given in parentheses. The Chi-square test of model fit for the LGC model: $\chi^2(25) = 37.84(p = .95)$; RMSEA = 0.00. For the MLR model: $-2 \log \text{likelihood} = 3346.114$.

The first column of Table 2 presents the relevant parameters; the second and third columns show the parameter estimates of respectively the MLR, and LGC model.

As one can see in Table 2 the parameter estimates are the same and, consequently, both approaches would lead to the same substantive conclusions. According to the overall measure of fit provided by SEM, the model seems to fit the data quite well. Thus, the conclusions can be summarized as follows. After controlling for the effect of the covariates, a mean growth curve emerges with an initial level of 9.89 and a growth rate of 1.96. The significant variation between the subjects around these mean values implies that subjects start their growth process at different values and grow subsequently at different rates. The correlation between initial level and growth rate is zero. In other words, the initial level has no predictive value for the growth rate. Intelligence has a positive effect on both the initial level and growth rate, leading to the conclusion that children who are more intelligent show a higher score at the first measurement occasion and a greater increase in language acquisition than children with lower intelligence. Emotional well-being explains the time-specific deviations from the mean growth curve. That is, children with a higher emotional well-being at a specific time point show a higher score on language acquisition than is predicted by their growth curve.

Dichotomous and Ordinal Data

Both conventional structural equation modeling and multilevel regression analysis assume that the outcome variable(s) are continuous and have a (multivariate) normal distribution. In practice, many variables are measured as ordinal categorical variables, for example, the responses on a five- or seven-point Likert attitude question. Often, researchers treat such variables as if they were continuous and normal variables. If the number of response categories is fairly large and the response distribution is symmetric, treating these variables as continuous normal variable appears to work quite well. For instance, Bollen and Barb [2] show in a simulation study that if bivariate normal variables are categorized into at least five response categories, the differences between the correlation between the original variables and the correlation of the categorized variables is small (see **Categorizing Data**). Johnson and Creech [7] show that this also holds for parameter estimates and model fit. However, when the number of categories is smaller than five, the distortion becomes sizable. It is clear that such variables require special treatment.

A Categorical ordinal variable can be viewed as a crude observation of an underlying latent variable. The same model that is used for the continuous variables is used, but it is assumed to hold for the underlying latent response. The residuals are assumed to have a standard normal distribution, or a logistic distribution. The categories of the ordinal variable arise from applying thresholds to the latent continuous variable. Assume that we have an ordered categorical variable with three categories, for example, 'disagree', 'neutral', and 'agree.' The relation of this variable to the underlying normal latent variable is depicted in Figure 2.

The position on the latent variable determines which categorical response is observed. Specifically,

$$y_i = \begin{cases} 1, & \text{if } y_i^* \leq \tau_1 \\ 2, & \text{if } \tau_1 < y_i^* \leq \tau_2 \\ 3, & \text{if } \tau_2 < y_i^*, \end{cases} \quad (3)$$

where y_i is the observed categorical variable, y_i^* is the latent continuous variable, and τ_1 and τ_2 are the thresholds. Note that a dichotomous variable only has one threshold, which becomes the intercept in a regression equation.

To analyze ordered categorical data in a multilevel regression context, the common approach is

Figure 2 Illustration of two thresholds underlying a three-category variable

to assume a normal or a logistic distribution (*see Catalogue of Probability Density Functions*). There are several estimation methods available; most software relies on a Taylor series approximation to the likelihood, although some software is capable of numerical integration of the likelihood. For a discussion of estimation in nonnormal multilevel models computational details, we refer to the literature, for example [4, 20]. The common approach in structural equation modeling is to estimate **polychoric correlations**, that is, the correlations between the underlying latent responses, and apply conventional SEM methods. This approach also assumes a standard normal distribution for the residuals. For statistical issues and computational details, we refer to the literature, for example [1, 8] (*see Structural Equation Modeling: Categorical Variables*). The important point here for both types of modeling is that when the number of categories of an outcome variable is small, using an analysis approach that assumes continuous variables may lead to strongly biased results.

To give an indication of the extent of the bias, the outcome variables of the language acquisition example were dichotomized on their common median. This leads to a data set where the number of ‘zero’ and ‘one’ scores on the four Y variables taken together is 50% each, with the proportion of ‘one’ scores goes up from 0.04 through 0.44 at the first occasion to 0.72 to 0.81 at the last occasion. Table 3 presents the results of three multilevel analyses for a model with a linear random effect for time: (1) **Maximum likelihood estimation** on a standardized continuous outcome Z (mean zero and variance one across Y1 to Y4) assuming normality, (2) Maximum Likelihood estimation on the dichotomized outcome D assuming normality, and (3) approximate Maximum Likelihood estimation on the dichotomized outcome D assuming a logistic model and using a Laplace approximation (Laplace6 in HLM5, [22]).

The parameter estimates are different across all three methods. This is not surprising, because the Z -scores are standardized to a mean of 0 and a variance of 1, the dichotomous variables have an overall mean

Table 3 Estimates of the parameters of (1), using multilevel regression and different estimation methods

Parameter	ML on Z assuming normality	ML on D assuming normality	Approximate ML on D assuming logistic
<i>Fixed Part</i>			
ν_0	-0.82	0.11	-2.44
ν_1	0.54	0.26	1.80
<i>Random part</i>			
σ_ϵ^2	0.07	0.10	—
σ_0^2	0.07	0.01	0.24
σ_1^2	0.12	0.01	0.60
σ_{01}	0.03	0.01	0.38

of 0.5 and a variance of 0.25, and the underlying continuous variable y^* has a mean of 0 and a residual variance of approximately 3.29. However, statistical tests on the variance components lead to drastically different conclusions. An ordinary likelihood-ratio test on the variances is not appropriate, because the null-hypothesis is a value that lies on the boundary of the parameter space. Instead, we apply the chi-square test described by Raudenbush and Bryk [21], which is based on the residuals. The multilevel regression analysis on the continuous Z -scores leads to significant variance components ($p < 0.01$). The multilevel logistic regression analysis on the dichotomized D -scores leads to variance components that are also significant ($p < 0.01$). On the other hand, the multilevel regression analysis on the dichotomized D -scores using standard Maximum Likelihood estimation for continuous outcomes, leads to variance components that are *not* significant ($p > 0.80$). Thus, for our example data, using standard Maximum Likelihood estimation assuming a continuous outcome on the dichotomized variable leads to substantively different and in fact misleading conclusions.

Extensions

The model in (1) can be extended in a number of ways. We will describe some of these extensions in this section separately, but they can in fact be combined in one model.

Extending the Number of Levels

First, let us assume that we have collected data on several occasions from individuals within classes, and that there are (systematic) differences between classes in intercept and slope. The model in (1) can easily account for such a ‘three-level’ structure by adding the class-specific subscript j . The model then becomes:

$$\begin{aligned} y_{tij} &= \lambda_{0t}\eta_{0ij} + \lambda_{1t}\eta_{1ij} + \gamma_{2t}x_{tij} + \varepsilon_{tij} \\ \eta_{0ij} &= v_{0j} + \gamma_{0i}z_i + \zeta_{0ij} \\ \eta_{1ij} &= v_{1j} + \gamma_{1i}z_i + \zeta_{1ij} \\ v_{0j} &= v_0 + \zeta_{2j} \\ v_{1j} &= v_1 + \zeta_{3j}, \end{aligned} \quad (4)$$

and reflects the fact that the mean intercept and slope (v_{0j} and v_{1j} , respectively) may be different across classes. Note that (4) turns into (1) if ζ_{2j} and ζ_{3j} are constrained to zero. Incorporating class-level covariates and additional higher levels in the hierarchy are straightforward.

Extending the Measurement Model

Secondly, the model in (1) can be easily extended to include multiple indicators of a construct at each occasion explicitly. Essentially this extension merges the growth curve model with a measurement (latent factor) model at each occasion. For example if y_{ti} represented a mean score over R items, we may recognize that $y_{ti} = \sum_{r=1}^R y_{rti}/m$. Instead of modeling observed item parcels, the R individual items y_{rti} can be modeled directly. That is, to model them, explicitly, as indicators of a latent construct or factor at each measurement occasion. A growth model may then be constructed to explain the variance and covariance among the first-order latent factors. This approach has been termed *second-order growth modeling* in contrast to first-order growth modeling on the observed indicators. Different names for the same model are ‘curve-of-factors model’ and ‘multiple indicator latent growth model’ [12]. Note that modeling multiple indicators in a longitudinal setting requires a test on the structure of the measurements, that is a test of measurement invariance or factorial invariance [1, 8]. The model incorporating all y_{rti} explicitly then becomes:

$$\begin{aligned} y_{rti} &= \alpha_r + \lambda_r\eta_{ti} + \varepsilon_{ri} \\ \eta_{ti} &= \lambda_{0t}\eta_{0i} + \lambda_{1t}\eta_{1i} + \gamma_{2t}x_{ti} + \zeta_{ti} \\ \eta_{0i} &= v_0 + \gamma_{0i}z_i + \zeta_{0i} \\ \eta_{1i} &= v_1 + \gamma_{1i}z_i + \zeta_{1i}, \end{aligned} \quad (5)$$

where α_r and λ_r represent, respectively, the item-specific intercept and factor loading of item r , and ε_{ri} is a residual. η_{ti} is an individual and time-specific latent factor corresponding to y_{ti} of Model (1), ζ_{ti} is a random deviation corresponding to ε_{ti} of Model (1). The growth curve model is subsequently built on the latent factor scores η_{ti} with λ_{1t} representing the time of measurement and λ_{0t} a constant equal to the value of 1. This model thus allows for a separation of measurement error ε_{ri} and individual time-specific

deviation ζ_{ti} . In Model (1) these components are confounded in ε_{ti} .

Nonlinear Growth

The model discussed so far assumes linear growth. The factor time is incorporated explicitly in the model by constraining λ_{1t} in (1) explicitly to known values to represent the occasions at which the subjects are measured. This is, however, not a necessary restriction; it is possible to estimate a more general, that is nonlinear, model in which values of λ_{1t} are estimated (see **Nonlinear Mixed Effects Models; Nonlinear Models**). Thus, instead of constraining λ_{1t} to, for example $[0, 1, 2, 3 \dots T]$, some elements are left free to be estimated, providing information on the shape of the growth curve. For purposes of identification, at least two elements of λ_{1t} need to be fixed. The remaining values are then estimated to provide information on the shape of the curve; λ_{1t} then becomes $[0, 1, \lambda_{12}, \lambda_{13}, \dots, \lambda_{1T-1}]$. So, essentially, a linear model is estimated, while the nonlinear interpretation comes from relating the estimated λ_{1t} to the real time frame [13, 24]. The transformation of λ_{1t} to the real time frame gives the nonlinear interpretation.

Further Extensions

Further noteworthy extensions of the standard growth model in (1) which we will briefly sum up here are:

- The assumption of independent and identically distributed residuals can be relaxed. In other words, the model in (1) may incorporate a more complex type of residual structure. In fact, any type of residual structure can be implemented, provided the resulting model is identified.
- As stated earlier, the assumption that all individuals have been measured at the same measurement occasions as implied by Model (1) can be relaxed by giving λ_{1t} in (1) an individual subscript i . λ_{1ti} can subsequently be partly, or even completely different across individuals. However, using LGC modeling requires that we treat different λ_{1ti} 's across subjects as a balanced design with missing data (i.e., that not all subjects have been measured at all occasions), and assumptions about the missing data mechanism need to be made.

- Growth mixture modeling provides an interesting extension of conventional growth curve analysis. By incorporating a categorical latent variable it is possible to represent a mixture of subpopulations where population membership is not known but instead must be inferred from the data [15, 16, 18]. See Li et al. [10], for a didactic example of this methodology.

Estimation and Software

When applied to longitudinal data as described above, the MLR and LGC model are identical; they only differ in their representation. However, these models come from different traditions, and the software was originally developed to analyze different problems. This has consequences for the way the data are entered into the program, the choices the analyst must make, and the ease with which specific extensions of the model are handled by the software.

LGC modeling is a special case of the general approach known as structural equation modeling (SEM). Structural equation modeling is inherently a multivariate analyst method, and it is therefore straightforward to extend the basic model with other (latent or observed) variables. Standard SEM software abounds with options to test the fit of the model, compare groups, and constrain parameters within and across groups. This makes SEM a very flexible analysis tool, and LGC modeling using SEM shows this flexibility. Typically, the different measurement occasions are introduced as separate variables. Time-varying covariates are also introduced as separate variables that affect the outcome measures at the corresponding measurement occasions. Time invariant covariates are typically incorporated in the model by giving these an effect on the latent variables that represent the intercept or the slope. However, it is also possible to allow the time invariant covariates to have direct effects on the outcome variables at each measurement occasion. This leads to a different model. In LGC modeling using SEM, it is a straightforward extension to model effects of the latent intercept and slope variables on other variables, including analyzing two LGC trajectories in one model and investigating how their intercepts and slopes are related.

The flexibility of LGC analysis using SEM implies that the analyst is responsible for ensuring that the

model is set up properly. For instance, one extension of the basic LGC model discussed in the previous section is to use a number of indicators for the outcome measure and extend the model by including a measurement model. In this situation, the growth model is modeled on the consecutive latent variables. To ensure that the measurement model is invariant over time, the corresponding factor loadings for measurements across time must be constrained to be equal. In addition, since the LGC model involves changes in individual scores and the overall mean across time, means and intercepts are included in the model, and the corresponding intercepts must also be constrained equal over time.

Adding additional levels to the model is relatively difficult using the SEM approach. Muthén [14] has proposed a limited information Maximum Likelihood method to estimate parameters in two-level SEM. This approach works well [6], and can be implemented in standard SEM software [5]. Since the LGC model can be estimated using standard SEM, two-level SEM can include a LGC model at the individual (lowest) level, with groups at the second level. However, adding more levels is cumbersome in the SEM approach.

Multilevel Regression (MLR) is a univariate method, where adding an extra (lowest) level for the variables allows analysts to carry out multivariate analyses. So, growth curve analysis using MLR is accomplished by adding a level for the repeated measurement occasions. Most MLR software requires that the data matrix is organized by having a separate row for each measurement occasion within each individual, with the time invariant individual characteristics repeated for occasions within the same individual. Adding time-varying or time invariant covariates to the model is straightforward; they are just added as predictor variables. Allowing the time invariant covariates to have direct effects on the outcome variables at each measurement occasion is more complicated, because in the MLR approach this requires specifying interactions of these predictors with dummy variables that indicate the measurement occasions.

Adding additional levels is simple in MLR; after all, this is what the software was designed for. The maximum number of levels is defined by software restrictions; the current record is MLwiN [20], which is designed to handle up to 50 levels. This may seem excessive, but many special analyses are set up in

multilevel regression software by including an extra level. This is used, for instance, to model multivariate outcomes, cross-classified data, and specify measurement models. For such models, a nesting structure of up to five levels is not unusual, and not all multilevel regression software can accommodate this.

The MLR model is more limited than SEM. For instance, it is not possible to let the intercept and slopes act as predictors in a more elaborate path model. The limitations show especially when models are estimated that include latent variables. For instance, models with latent variables over time that are indicated by observed variables, easy to specify in SEM, can be set up in MLR using an extra variable level. At this (lowest) level, dummy variables are used to indicate variables that belong to the same construct at different measurement occasions. The regression coefficients for these dummies are allowed to vary at the occasion level, and they are interpreted as latent variables in a measurement model. However, this measurement model is more restricted than the measurement in the analogous SEM. In the MLR approach, the measurement model is a factor model with equal loadings for all variables, and one common error variance for the unique factors. In some situations, for instance, when the indicators are items measured using the same response scale, this restriction may be reasonable. It also ensures that the measurement model is invariant over time. The important issue is of course that this restriction cannot be relaxed in the MLR model, and it cannot be tested.

Most modern structural equation modeling software can be used to analyze LGC models. If the data are unbalanced, either by design or because of panel attrition, it is important that the software supports analyzing incomplete data using the raw Likelihood. If there are categorical response variables, it is important that the software supports their analysis. At the time of writing, only Muthén's software *Mplus* supports the combination of categorical incomplete data [17].

Longitudinal data can be handled by all multilevel software. Some software supports analyzing specific covariance structures over time, such as autoregressive models. When outcome variables may be categorical, there is considerable variation in the estimation methods employed. Most multilevel regression relies on Taylor series linearization, but increasingly numerical integration is used, which is regarded as more accurate.

A recent development in the field is that the distinction between MLR and LGC analysis is blurring. Advanced structural equation modeling software is now incorporating some multilevel features. *Mplus*, for example, goes a long way towards bridging the gap between the two approaches [15, 16]. On the other hand MLR software is incorporating features of LGC modeling. Two MLR software packages allow linear relations between the growth parameters: HLM [22] and GLLAMM [19]. HLM offers a variety of residual covariance structures for MLR models. The GLLAMM framework is especially powerful; it can be viewed as a multilevel regression approach that allows factor loadings, variable-specific unique variances, as well as structural equations among latent variables (both factors and random coefficients). In addition, it supports categorical and incomplete data. As the result of further developments in both statistical models and software, the two approaches to growth curve modeling may in time merge (*see Software for Statistical Analyses; Structural Equation Modeling: Software*).

Discussion

Many methods are available for the analysis of longitudinal data. There is no single preferred procedure, since different substantial questions dictate different data structures and statistical models. This entry focuses on growth curve analysis. Growth curve analysis, and its SEM variant latent growth curve analysis, has advantages for the study of change if it can be assumed that change is systematically related to the passage of time. Identifying individual differences in change, as well as understanding the process of change are considered critical issues in developmental research by many scholars. Growth curve analysis explicitly reflects on both intra-individual change and interindividual differences in such change.

In this entry, we described the general growth curve model and discussed differences between the multilevel regression approach and latent growth curve analysis using structural equation modeling. The basic growth curve model has a similar representation, and gives equivalent results in both approaches. Differences exist in the ways the model can be extended. In many instances, latent growth curve analysis is preferred because of its greater flexibility. Multilevel Regression is preferable if the

growth model must be embedded in a larger number of hierarchical data levels.

Multiple Baseline Designs

Single-case designs were developed to allow researchers to examine the effect of a treatment for a single case, where the case may be an individual participant or a group such as a class of students. Multiple-baseline designs [1] are an extension of the most basic single-case design, the AB, or interrupted time-series design. With an AB design, the researcher repeatedly measures the behavior of interest prior to intervention. These observations become the baseline phase (A). The researcher then introduces a treatment and continues to repeatedly measure the behavior, creating the treatment phase (B) of the design. If a change in behavior is observed, some may question whether the change was the result of the treatment or whether it resulted from maturation or some event that happened to coincide with treatment implementation. To allow researchers to rule out these alternative explanations for observed changes, more elaborate single-case designs were developed.

Multiple-baseline designs extend the AB design, such that a baseline phase (A) and treatment phase (B) are established for multiple participants, multiple behaviors, or multiple settings. The initiation of the treatment phases is staggered across time creating baselines of different lengths for the different participants, behaviors, or settings. The general form of the design with 12 observations and 4 baselines is presented in Figure 1.

To further illustrate the logic of this design, a graphical display of data from a multiple baseline across participant design is presented in Figure 2. When the first participant enters treatment, there is a notable change in behavior for this participant. The other participant, who is still in baseline, does not show appreciable changes in behavior when the treatment is initiated with the first participant. This makes history or maturational effects less plausible as explanations for why the first participant's behavior

changed. Put another way, when changes are due to history or maturation, we would anticipate change for each participant, but we would not expect those changes to stagger themselves across time in a manner that happened to coincide with the staggered interventions.

Applications

The multiple-baseline design is often employed in applied clinical and educational settings. However, its application may be extended to a variety of other disciplines and situations. The following are examples in which this design may be utilized:

- Educators might find the multiple baseline across individuals to be suitable for studying methods for reducing disruptive behaviors of students in the classroom.
- Psychologists might find the multiple baseline across behaviors to be suitable for investigating the effects of teaching children with autism to use socially appropriate gestures in combination with oral communication.
- Counselors might find the multiple baseline across participants to be suitable for studying the effects of training staff in self-supervision and uses of empathy in counseling situations.
- Therapists might find the multiple baseline across groups to be suitable for examining the effectiveness of treating anxiety disorders, phobias, and obsessive-compulsive disorders in adolescents.
- Retailers and grocery stores might find the multiple-baseline design across departments to be suitable for studying training effects on cleaning behaviors of employees.
- Teacher preparation programs might find the multiple baseline across participants to be suitable for examining the result of specific teaching practices.

- Medical practitioners or social workers might find the multiple baseline across behaviors to be suitable for studying the impact of teaching child care and safety skills to parents with intellectual disabilities.

Design Strengths and Weaknesses

The widespread use of multiple-baseline designs can be attributed to a series of practical and conceptual strengths. The multiple-baseline design allows researchers to focus extensively on a single participant or on a few participants. This may be advantageous in contexts where researchers wish to study cases that are relatively rare, when researchers are implementing particularly complex and time-consuming treatments, and when they are devoted to showing effects on specific individuals. Among single-case designs, the multiple-baseline design allows researchers to consider history and maturation effects without requiring them to withdraw the treatment. This can be seen as particularly valuable in clinical settings where it may not be ethical to withdraw an effective treatment.

Multiple-baseline designs provide relatively strong grounds for causal inferences when treatment effects can be seen that coincide with the unique intervention times for each participant, behavior, or setting. Things are less clear when there is a lack of independence between baselines so that treatment of one baseline

impacts another, or when treatment effects are not consistent across participants, behaviors, or settings. It should also be noted that the evidence for inferring a treatment effect for any one participant tends to be established less clearly than it could be in a single-case design involving a reversal. Finally, relative to group designs, the multiple-baseline design involves relatively few participants and thus there is little means for establishing generalizability.

Design Issues

More Complex Designs

The basic multiple-baseline design can be extended to have a more complex between series structure. For example, a researcher could conduct a multiple-baseline design across participants and behaviors by studying three behaviors of each of three participants. A researcher could also extend the multiple-baseline design by using a more complex within series structure. For example, a researcher conducting a multiple-baseline design across participants may for each participant include a baseline phase, followed by a treatment phase, followed by a second baseline phase. Whether one is considering the basic multiple-baseline design or a more complex extension, there are several additional design features that should be considered, including the number of baselines, the number of observations to be collected in each time series, and the decision about when to intervene within each series.

Number of Baselines

Multiple-baseline designs need to include at least two baselines, and the use of three or four baselines is more common. Assuming other things are equal, it is preferable to have greater numbers of baselines. Having more baselines provides a greater number of replications of the effect, and allows greater confidence that the observed effect in a particular time series was the result of the intervention.

Number of Observations

The number of observations within a time series varies greatly from one multiple-baseline study to the next. One study may have a phase with two

or three observations, while another may have more than 30 observations in each phase. When other things are equal, greater numbers of observations lead to stronger statements about treatment effects. The number of observations needed depends heavily on the amount of variation in the baseline data and the size of the anticipated effect. Suppose that a researcher wishes to intervene with four students that consistently spend no time on a task during a particular activity (i.e., 0% is observed for each baseline observation). Suppose further that the intervention is expected to increase the time on the task to above 80%. Under these conditions, a few observations within each phase is ample. However, if the baseline observations fluctuated between 0% and 80% with an average of 40% and the hope was to move the average to at least 60% for each student, many more observations would be needed.

Placement of Intervention Points

Systematic Assignment. The points at which the researcher will intervene can be established in several different ways. In some cases, the researcher simply chooses the points *a priori* on the basis of obtaining an even staggering across time. For example, the researcher may choose to intervene for the four baselines at times 4, 6, 8, and 10 respectively. This method seems to work well when baseline observations are essentially constant. Under these conditions, temporal stability is assumed and the researcher uses what has been referred to as the scientific solution to causal inference. When baseline observations are more variable, inferences become substantially more difficult and one may alter the method of assigning intervention points to facilitate drawing treatment effect inferences.

Response-guided Assignment. One option is to use a response-guided strategy where the data are viewed and intervention points are chosen on the basis of the emerging data. For example, a researcher gathering baseline data on each of the four individuals may notice variability in each participant's behavior. The researcher may be able to identify sources of this variability and make adjustments to the experiment to control the identified factors. After controlling these factors, the baseline data may stabilize, and the researcher may feel comfortable intervening with the first participant. The researcher would continue

watching the accumulating observations waiting until the data for the first participant demonstrated the anticipated effect. At this point, if the baseline data were still stable for the other three participants, the researcher would intervene with the second participant. Interventions for the third and fourth participants would be made in a similar manner, each time waiting until the data had shown a clear pattern before beginning the next treatment phase.

The response-guided strategy works relatively well when initial sources of variability to the baseline data can be identified and controlled. Variability may be resulting from unreliability in the measurement process that could be corrected with training, or it may be resulting from changes in the experimental conditions. As examples, variation may be associated with changes in the time of the observation, changes in the activities taking place during the observation period, changes in the people present during the observation period, or changes in the events preceding the observation period. By further standardizing conditions, variation in the baseline data can be reduced. If near constancy can be obtained in the baseline data, temporal stability can be assumed, and treatment effects can be readily seen.

When baseline variability cannot be controlled, one may turn to statistical methods for making treatment effect inferences. Interestingly, the response-guided strategy for establishing intervention points can lead to difficulties in establishing inferences statistically. Researchers wishing to make statistical inferences may turn to an approach that includes some form of random assignment.

Random Assignment. One approach is to randomly assign participants to designated intervention times (*see Randomization*). To illustrate, consider a researcher who plans to conduct a multiple-baseline study across participants where 12 observations will be gathered on each of the four participants. The researcher could decide that the interventions would occur on the 4th, 6th, 8th, and 10th point in time. The researcher could then randomly decide which participant would be treated at the 4th point in time, which would be treated at the 6th point in time, which on the 8th, and which on the 10th.

A second method of randomization would be to randomly select an intervention point for a participant under the restriction that there would be at least n observations in each phase. For example, the

researcher could randomly choose a time point for each participant under the constraint that the chosen point would fall between the 4th and 10th observation. It may turn out that a researcher chooses the interventions for the four participants to coincide with the 8th, 4th, 7th, and 5th observations, respectively. This leads to more possible assignments than the first method, but could possibly lead to the assignment of all interventions to the same point in time. This would be inconsistent with the temporal staggering, which is a defining feature in the multiple-baseline design, so one may wish to further restrict the randomization so this is not possible.

One way of doing this is to randomly choose intervention times under greater constraints and then randomly assign participants to intervention times. For example, a researcher could choose four intervention times by randomly choosing the 3rd or 4th, then randomly choosing the 5th or 6th, then randomly choosing the 7th or 8th, and then randomly choosing the 9th or 10th. The four participants could then be randomly assigned to these four intervention times. Finally, one could consider coupling one of these randomization methods with a response-guided strategy. For example, a researcher could work to control sources of baseline variability, and then make the random assignment after the data had stabilized as much as possible.

Analysis

Researchers often start their analysis by constructing a graphical display of the multiple-baseline data. In many applications, a visual analysis of the graphical display is the only analysis provided. There are, however, a variety of additional methods available to help make inferences about treatment effects in multiple-baseline studies.

If one makes intervention assignments randomly, then it is possible to use a randomization test to make

an inference about the presence of a treatment effect. Randomization tests [2] have been developed for each of the randomization strategies previously described, and these tests are statistically valid even when history or maturational effects have influenced the data. It is important to note, however, that these tests do not lead to inferences about the size of the treatment effect. When baseline data are variable, effect size inferences are often difficult and researchers should consider statistical modeling approaches.

A variety of statistical models are available for time series data [3], including models with a relatively simple assumed error structure, such as a standard regression model that assumes an independent error structure, to more complex time series models that have multiple parameters to capture dependencies among the errors, such as an autoregressive moving average model. Different error structure assumptions will typically lead to different estimated standard errors and potentially different inferential statements about the size of treatment effects. Consequently, care should be taken to establish the credibility of the assumed statistical model, which often requires a relatively large number of observations.

Multiple Comparison Procedures

Introduction

When more than two groups are compared for the effects of a treatment variable, researchers frequently adopt multiple comparison procedures (MCPs) in order to specify the exact nature of the treatment effects. Comparisons between two groups, pairwise comparisons, are frequently of interest to applied researchers, comparisons such as examining the effects of two different types of drugs, from a set of groups administered different drugs, on symptom dissipation. Complex comparisons, nonpairwise comparisons, the comparison of say one group (e.g., a group receiving a placebo instead of an active drug) to the average effect of two other groups (e.g., say two groups receiving some amount of the drug—50 and 100 mg) are also at times of interest to applied researchers. In both cases, the intent of the researcher is to examine focused questions about the nature of the treatment variable, in contrast to the answer provided by an examination of a global hypothesis through an omnibus test statistic (e.g., say, the use of the analysis of variance F test in order to determine if there is an effect of $J > 2$ ($j = 1, \dots, J$) different types of drugs on symptom dissipation).

A recent survey of statistical practices of behavioral science researchers indicates that the Tukey [60] and Scheffé [55] MCPs are very popular methods for conducting pairwise and complex comparisons, respectively (Keselman et al., [28]). However, behavioral science researchers now have available to them a plethora of procedures that they can choose from when their interest lies in conducting pairwise and complex comparisons among their treatment group means. In most cases, these newer procedures will provide either a test that is more insensitive, that is more robust, to the nonconformity of applied data to the derivational assumptions (i.e., homogeneity of population variances and normally distributed data) of the classical procedures (Tukey and Scheffé) or will provide greater sensitivity (statistical **power**) to detect effects when they are present. Therefore, the purpose of our paper is to present a brief introduction to some of the newer methods for conducting multiple comparisons. Our presentation will predominately

be devoted to an examination of pairwise methods since researchers perform these comparisons more often than complex comparisons. However, we will discuss some methods for conducting complex comparisons among treatment group means. Topics that we briefly review prior to our presentation of newer MCPs will be methods of Type I error control and simultaneous versus stepwise multiple testing.

It is important to note that the MCPs that are presented in our paper were also selected for discussion, because researchers can, in most cases, obtain numerical results with a statistical package, and in particular, through the SAS [52] system of computer programs. The SAS system presents a comprehensive up-to-date array of MCPs (see [65]). Accordingly, we acknowledge at the beginning of our presentation that some of the material we present follows closely Westfall et al.'s presentation. However, we also present procedures that are not available through the SAS system. In particular, we discuss a number of procedures that we believe are either new and interesting ways of examining pairwise comparisons (e.g., the model comparison approach of Dayton [6]) or have been shown to be insensitive to the usual assumptions associated with some of the procedures discussed by Westfall et al. (e.g., MCPs based on robust estimators).

Type I Error Control

Researchers who test a hypothesis concerning mean differences between two treatment groups are often faced with the task of specifying a significance level, or decision criterion, for determining whether the difference is significant. The level of significance specifies the maximum probability of rejecting the null hypothesis when it is true (i.e., committing a Type I error). As α decreases, researchers can be more confident that rejection of the null hypothesis signifies a true difference between population means, although the probability of not detecting a false null hypothesis (i.e., a Type II error) increases. Researchers faced with the difficult, yet important, task of quantifying the relative importance of Type I and Type II errors have traditionally selected some accepted level of significance, for example $\alpha = .05$.

However, determining how to control Type I errors is much less simple when multiple tests of significance (e.g., all possible pairwise comparisons between group means) will be computed. This is

2 Multiple Comparison Procedures

because when multiple tests of significance are computed, how one chooses to control Type I errors can affect whether one can conclude that effects are statistically significant or not.

The multiplicity problem in statistical inference refers to selecting the statistically significant findings from a large set of findings (tests) to support or refute one's research hypotheses. Selecting the statistically significant findings from a larger pool of results that also contain nonsignificant findings is problematic since when multiple tests of significance are computed, the probability that at least one will be significant by chance alone increases with the number of tests examined (*see Error Rates*).

Discussions on how to deal with multiplicity of testing have permeated many literatures for decades and continue to this day. In one camp are those who believe that the occurrence of any false positive must be guarded at all costs (see [13], [40], [48, 49, 50], [66]); that is, as promulgated by Thomas Ryan, pursuing a false lead can result in the waste of much time and expense, and is an error of inference that accordingly should be stringently controlled. Those in this camp deal with the multiplicity issue by setting α for the entire set of tests computed.

For example, in the pairwise multiple comparison problem, Tukey's [60] MCP uses a critical value wherein the probability of making at least one Type I error in the set of pairwise comparisons tests is equal to α . This type of control has been referred to in the literature as family-wise or experiment-wise (FWE) control. These respective terms come from setting a level of significance over all tests computed in an experiment, hence experiment-wise control, or setting the level of significance over a set (family) of conceptually related tests, hence FWE control. Multiple comparisonists seem to have settled on the family-wise label. As indicated, for the set of pairwise tests, Tukey's procedure sets a FWE for the family consisting of all pairwise comparisons.

Those in the opposing camp maintain that stringent Type I error control results in a loss of statistical power and consequently important treatment effects go undetected (see [47], [54], [72]). Members of this camp typically believe the error rate should be set per comparison (the probability of rejecting a given comparison) (hereafter referred to as the comparison-wise error-CWE rate) and usually recommend a five percent level of significance, allowing the overall error rate (i.e., FWE) to inflate with the number of tests

computed. In effect, those who adopt comparison-wise control ignore the multiplicity issue.

For example, a researcher comparing four groups ($J = 4$) may be interested in determining if there are significant pairwise mean differences between any of the groups. If the probability of committing a Type I error is set at α for each comparison (comparison-wise control = CWE), then the probability that at least one Type I error is committed over all $C = 4(4 - 1)/2 = 6$ pairwise comparisons can be much higher than α . On the other hand, if the probability of committing a Type I error is set at α for the entire family of pairwise comparisons, then the probability of committing a Type I error for each of the C comparisons can be much lower than α . Clearly then, the conclusions of an experiment can be greatly affected by the level of significance and unit of analysis over which Type I error control is imposed.

The FWE rate relates to a family (containing, in general, say k elements) of comparisons. A family of comparisons, as we indicated, refers to a set of conceptually related comparisons, for example, all possible pairwise comparisons, all possible complex comparisons, trend comparisons, and so on. As Miller [40] points out, specification of a family of comparisons, being self-defined by the researcher, can vary depending on the research paradigm. For example, in the context of a one-way design, numerous families can be defined: A family of all comparisons performed on the data, a family of all pairwise comparisons, a family of all complex comparisons. (Readers should keep in mind that if multiple families of comparisons are defined (e.g., one for pairwise comparisons and one for complex comparisons), then given that erroneous conclusions can be reached within each family, the overall Type I FWE rate will be a function of the multiple subfamily-wise rates.)

Specifying family size is a very important component of multiple testing. As Westfall et al. [65, p. 10] note, differences in conclusions reached from statistical analyses that control for multiplicity of testing (FWE) and those that do not (CWE) are directly related to family size. That is, the larger the family size, the less likely individual tests will be found to be statistically significant with family-wise control. Accordingly, to achieve as much sensitivity as possible to detect true differences and yet maintain control over multiplicity effects, Westfall et al. recommend that researchers 'choose smaller, more focused families rather than broad ones, and

(to avoid cheating) that such determination must be made *a priori* . . .’

Definitions of the CWE and FWE rates appear in many sources (e.g., see [34], [48], [40], [59], [60]).

Controlling the FWE rate has been recommended by many researchers (e.g., [16], [45], [48], [50], [60]) and is ‘the most commonly endorsed approach to accomplishing Type I error control’ [56, p. 577]. Keselman et al. [28] report that approximately 85 percent of researchers conducting pairwise comparisons adopt some form of FWE control.

Although many MCPs purport to control FWE, some provide ‘strong’ FWE control while others only provide ‘weak’ FWE control. Procedures are said to provide strong control if FWE is maintained across all null hypotheses; that is, under the complete null configuration ($\mu_1 = \mu_2 = \dots = \mu_J$) and all possible partial null configurations (An example of a partial null hypothesis is $\mu_1 = \mu_2 = \dots = \mu_{J-1} \neq \mu_J$). Weak control, on the other hand, only provides protection for the complete null hypothesis, that is, not for all partial null hypotheses as well.

The distinction between strong and weak FWE control is important because as Westfall et al. [65] note, the two types of FWE control, in fact, control different error rates. Weak control only controls the Type I error rate for falsely rejecting the complete null hypothesis and accordingly allows the rate to exceed, say 5%, for the composite null hypotheses. On the other hand, strong control sets the error rate at, say 5%, for all (component) hypotheses. For example, if $CWE = 1 - (1 - 0.05)^{1/k}$, the family-wise rate is controlled in a strong sense for testing k independent tests. Examples of MCPs that only weakly control FWE are the Newman [41] Keuls [33] and Duncan [8] procedures.

As indicated, several different error rates have been proposed in the multiple comparison literature. The majority of discussion in the literature has focused on the FWE and CWE rates (e.g., see [34], [48], [40], [59], [60]), although other error rates, such as the false discovery rate (FDR) also have been proposed (e.g., see Benjamini & Hochberg [2]).

False Discovery Rate Control. Work in the area of multiple hypothesis testing is far from static, and one of the newer interesting contributions to this area is an alternative conceptualization for defining errors in the multiple-testing problem; that is the FDR, presented by Benjamini and Hochberg [2]. FDR is defined

by these authors as the expected proportion of the number of erroneous rejections to the total number of rejections, that is, it is the expected proportion of false discoveries or false positives.

Benjamini and Hochberg [2] provide a number of illustrations where FDR control seems more reasonable than family-wise or comparison-wise control. Exploratory research, for example, would be one area of application for FDR control. That is, in new areas of inquiry where we are merely trying to see what parameters might be important for the phenomenon under investigation, a few errors of inference should be tolerable; thus, one can reasonably adopt the less stringent FDR method of control which does not completely ignore the multiple-testing problem, as does comparison-wise control, and yet, provides greater sensitivity than family-wise control. Only at later stages in the development of our conceptual formulations does one need more stringent family-wise control. Another area where FDR control might be preferred over family-wise control, suggested by Benjamini and Hochberg [2], would be when two treatments (say, treatments for dyslexia) are being compared in multiple subgroups (say, children of different ages). In studies of this sort, where an overall decision regarding the efficacy of the treatment is not of interest but, rather where separate recommendations would be made within each subgroup, researchers likely should be willing to tolerate a few errors of inference and accordingly would profit from adopting FDR rather than family-wise control.

Very recently, use of the FDR criterion has become widespread when making inferences in research involving the human genome, where family sizes in the thousands are common. See the review by Dudoit, Shaffer and Boldrick [7], and references contained therein.

Since multiple testing with FDR tends to detect more significant differences than testing with FWE, some researchers may be tempted to automatically prefer FDR control to FWE control. We caution that researchers who use FDR should be obligated to explain, in terms of the definitions of the two criteria, why it is more appropriate to control FDR than FWE in the context of their research.

Types of MCPs

MCPs can examine hypotheses either simultaneously or sequentially. A simultaneous MCP conducts all

4 Multiple Comparison Procedures

comparisons regardless of whether the omnibus test, or any other comparison, is significant (or not significant) using a constant critical value. Such procedures are frequently referred to as simultaneous test procedures (STPs) (see Einot & Gabriel [11]). A sequential (stepwise) MCP considers either the significance of the omnibus test or the significance of other comparisons (or both) in evaluating the significance of a particular comparison; multiple critical values are used to assess statistical significance. MCPs that require a significant omnibus test in order to conduct pairwise comparisons have been referred to as protected tests.

MCPs that consider the significance of other comparisons when evaluating the significance of a particular comparison can be either step-down or step-up procedures. Step-down procedures begin by testing the most extreme test statistic and nonsignificance of the most extreme test statistics implies nonsignificance for less extreme test statistics. Step-up procedures begin by testing the least extreme test statistic and significance of least extreme test statistics can imply significance for larger test statistics. In the equal sample sizes case, if a smaller pairwise difference is statistically significant, so is a larger pairwise difference, and conversely. However, in the unequal sample-size cases, one can have a smaller pairwise difference be significant and a larger pairwise difference nonsignificant, if the sample sizes for the means comprising the smaller difference are much larger than the sample sizes for the means comprising the larger difference.

One additional point regarding STP and stepwise procedures is important to note. STPs allow researchers to examine simultaneous intervals around the statistics of interest whereas stepwise procedures do not (see, however, [4]).

Preliminaries

A mathematical model that can be adopted when examining pairwise and/or complex comparisons of means in a one-way completely randomized design is:

$$Y_{ij} = \mu_j + \epsilon_{ij}, \quad (1)$$

where Y_{ij} is the score of the i th subject ($i = 1, \dots, n$) in the j th ($j = 1, \dots, J$) group ($\sum_j n = N$), μ_j is the j th group mean, and ϵ_{ij} is the random error for the i th subject in the j th group. In the typical application

of the model, it is assumed that the ϵ_{ij} s are normally and independently distributed and that the treatment group variances (σ_j^2 s) are equal. Relevant sample estimates include

$$\begin{aligned} \hat{\mu}_j &= \bar{Y}_j = \sum_{i=1}^n \frac{Y_{ij}}{n} \text{ and } \hat{\sigma}^2 = \text{MSE} \\ &= \sum_{j=1}^J \sum_{i=1}^n \frac{(Y_{ij} - \bar{Y}_j)^2}{J(n-1)}. \end{aligned} \quad (2)$$

Pairwise Comparisons

A **confidence interval** for a pairwise difference $\mu_j - \mu_{j'}$

$$\bar{Y}_j - \bar{Y}_{j'} \pm c_\alpha \hat{\sigma} \sqrt{\frac{2}{n}}, \quad (3)$$

where c_α is selected such that $\text{FWE} = \alpha$. In the case of all possible pairwise comparisons, one needs a c_α for the set such that they simultaneously surround the true differences with a specified level of significance. That is, for all $j \neq j'$, c_α must satisfy

$$\begin{aligned} P \left(\bar{Y}_j - \bar{Y}_{j'} - c_\alpha \hat{\sigma} \sqrt{\frac{2}{n}} \leq \mu_j - \mu_{j'} \right. \\ \left. \leq \bar{Y}_j - \bar{Y}_{j'} + c_\alpha \hat{\sigma} \sqrt{\frac{2}{n}} \right) = 1 - \alpha. \end{aligned} \quad (4)$$

A hypothesis for the comparison ($H_c : \mu_j - \mu_{j'} = 0$) can be examined with the test statistic:

$$t_c = \frac{\bar{Y}_j - \bar{Y}_{j'}}{(2 \text{MSE} / n)^{1/2}}. \quad (5)$$

MCPs that assume normally distributed data and homogeneity of variances are given below.

Tukey. Tukey [60] proposed a STP for all pairwise comparisons. Tukey's MCP uses a critical value obtained from the Studentized range distribution. In particular, statistical significance, with FWE control, is assessed by comparing

$$|t_c| \geq \frac{q(J, J(n-1))}{\sqrt{2}}, \quad (6)$$

where q is a value from the Studentized range distribution (see [34]) based on J means and $J(n-1)$ error degrees of freedom. Tukey's procedure can

be implemented in SASs [52] **generalized linear model (GLM)** program.

Tukey–Kramer [35]. It is also important to note that Tukey’s method, as well as other MCPs, can be utilized when group sizes are unequal. A pairwise test statistic for the unequal sample-size case would be

$$t_{j,j'} = \frac{\bar{Y}_j - \bar{Y}_{j'}}{\sqrt{MSE(1/n_j + 1/n_{j'})}} (j \neq j'). \quad (7)$$

Accordingly, the significance of a pairwise difference is assessed by comparing

$$|t_{j,j'}| > \frac{q(J, \Sigma_j(n_j-1))}{\sqrt{2}}. \quad (8)$$

Hayter [17] proved that the Tukey–Kramer MCP only approximately controls the FWE – the rate is slightly conservative, that is, the true rate of Type I error will be less than the significance level. The GLM procedure in SAS will automatically compute the Kramer version of Tukey’s test when group sizes are unequal.

Fisher–Hayter’s Two-stage MCP. Fisher [12] proposed conducting multiple t Tests on the C pairwise comparisons following rejection of the omnibus ANOVA null hypothesis (see [29], [34]). The pairwise null hypotheses are assessed for statistical significance by referring t_c to $t_{(\alpha/2, \nu)}$, where $t_{(\alpha/2, \nu)}$ is the upper $100(1 - \alpha/2)$ percentile from Student’s distribution with parameter ν . If the ANOVA F is nonsignificant, comparisons among means are not conducted; that is, the pairwise hypotheses are retained as null.

It should be noted that Fisher’s [12] least significant difference (LSD) procedure only provides Type I error protection via the level of significance associated with the ANOVA null hypothesis, that is, the complete null hypothesis. For other configurations of means not specified under the ANOVA null hypothesis (e.g., $\mu_1 = \mu_2 = \dots = \mu_{J-1} < \mu_J$), the rate of family-wise Type I error can be much in excess of the level of significance (Hayter [18]; Hochberg & Tamhane [20]; Keselman et al. [29]; Ryan, [51]).

Hayter [18] proposed a modification to Fisher’s LSD that would provide strong control over FWE. Like the LSD procedure, no comparisons are tested

unless the omnibus test is significant. If the omnibus test is significant, then H_c is rejected if:

$$|t_c| > \frac{q(J-1, \nu)}{\sqrt{2}}. \quad (9)$$

Studentized range critical values can be obtained through SASs PROBMC (see [65], p. 46).

It should be noted that many authors recommend Fisher’s two-stage test for pairwise comparisons when $J = 3$ (see [27], [37]). These recommendations are based on Type I error control, power and ease of computation issues.

Hochberg’s Sequentially Acceptive Step-up Bonferroni Procedure. In this procedure [19], the P values corresponding to the m statistics (e.g., t_c) for testing the hypotheses $H_1, \dots, H_m$ are ordered from smallest to largest. Then, for any $i = m, m-1, \dots, 1$, if $p_i \leq \alpha/(m-i+1)$, the Hochberg procedure rejects all $H_{i'} (i' \leq i)$. According to this procedure, therefore, one begins by assessing the largest P value, p_m . If $p_m \leq \alpha$, all hypotheses are rejected. If $p_m > \alpha$, then H_m is accepted and one proceeds to compare $p_{(m-1)}$ to $\alpha/2$. If $p_{(m-1)} \leq \alpha/2$, then all $H_i (i = m-1, \dots, 1)$ are rejected; if not, then $H_{(m-1)}$ is accepted and one proceeds to compare $p_{(m-2)}$ with $\alpha/3$, and so on.

Shaffer’s Sequentially Rejective Bonferroni Procedure that Begins with an Omnibus Test. Like the preceding procedure, the P values associated with the test statistics are rank ordered. In Shaffer’s procedure [57], however, one begins by comparing the smallest P value, p_1 , to α/m . If $p_1 > \alpha/m$, statistical testing stops and all pairwise contrast hypotheses ($H_i, 1 \leq i \leq m$) are retained; on the other hand, if $p_1 \leq \alpha/m$, H_1 is rejected and one proceeds to test the remaining hypotheses in a similar step-down fashion by comparing the associated P values to α/m^* , where m^* is equal to the maximum number of true null hypotheses, given the number of hypotheses rejected at previous steps. Appropriate denominators for each α -stage test for designs containing up to ten treatment levels can be found in Shaffer’s Table 2.

Shaffer [57] proposed a modification to her sequentially rejective Bonferroni procedure which involves beginning this procedure with an omnibus test. (Though MCPs that begin with an omnibus test frequently are presented with the F test, other

omnibus tests (e.g., a range statistic) can also be applied to these MCPs.) If the omnibus test is declared nonsignificant, statistical testing stops and all pairwise differences are declared nonsignificant. On the other hand, if one rejects the omnibus null hypothesis, one proceeds to test pairwise contrasts using the sequentially rejective Bonferroni procedure previously described, with the exception that p_m , the smallest P value, is compared to a significance level which reflects the information conveyed by the rejection of the omnibus null hypothesis. For example, for $m = 6$, rejection of the omnibus null hypothesis implies at least one inequality of means and, therefore, p_6 is compared to $\alpha/3$, rather than $\alpha/6$.

Benjamini and Hochberg's (BH) FDR Procedure.

In this procedure [2], the P values corresponding to the m pairwise statistics for testing the hypotheses $H_1, \dots, H_m$ are ordered from smallest to largest, that is, $p_1 \leq p_2 \leq \dots \leq p_m$, where $m = J(J-1)/2$. Let k be the largest value of i for which $p_i \leq i/m\alpha$, then reject all $H_i, i = 1, 2, \dots, k$. According to this procedure one begins by assessing the largest P value, p_m , proceeding to smaller P values as long as $p_i > i/m\alpha$. Testing stops when $p_k \leq k/m\alpha$.

Benjamini and Hochberg [3] also presented a modified (adaptive) (BH-A) version of their original procedure that utilizes the data to estimate the number of true H_c s. [The adaptive BH procedure has only been demonstrated, *not proven*, to control FDR, and only in the independent case.] With the original procedure, when the number of true null hypotheses (C_T) is less than the total number of hypotheses, the FDR rate is controlled at a level less than that specified (α).

To compute the Benjamini and Hochberg [2] procedure, the p_c -values are ordered (smallest to largest) $p_1, \dots, p_c$, and for any $c = C, C-1, \dots, 1$, if $p_c \leq \alpha(c/C)$, reject all $H_{c'} (c' \leq c)$. If all H_c s are retained, testing stops. If any H_c is rejected with the criterion of the BH procedure, then testing continues by estimating the slopes $S_c = (1 - p_c)/(C + 1 - c)$, where $c = 1, \dots, C$. Then, for any $c = C, C-1, \dots, 1$, if $p_c \leq \alpha(c/\hat{C}_T)$, reject all $H_{c'} (c' \leq c)$, where $\hat{C}_T = \min[(1/S^*) + 1, C]$, $[x]$ is the largest integer less than or equal to x and S^* is the minimum value of S_c such that $S_c < S_{c-1}$. If all $S_c > S_{c-1}$, S^* is set at C .

One disadvantage of the BH-A procedure, noted by both Benjamini and Hochberg [3] and Holland and Cheung [21], is that it is possible for an H_c to be rejected with $p_c > \alpha$. Therefore, it is suggested, by both authors, that H_c only be rejected if: (a) the hypothesis satisfies the rejection criterion of the BH-A; and (b) $p_c \leq \alpha$. To illustrate this procedure, assume a researcher has conducted a study with $J = 4$ and $\alpha = .05$. The ordered P values associated with the $C = 6$ pairwise comparisons are: $p_1 = .0014$, $p_2 = .0044$, $p_3 = .0097$, $p_4 = .0145$, $p_5 = .0490$, and $p_6 = .1239$. The first stage of the BH-A procedure would involve comparing $p_6 = .1239$ to $\alpha(c/C) = .05(6/6) = .05$. Since $.1239 > .05$, the procedure would continue by comparing $p_5 = .0490$ to $\alpha(c/C) = .05(5/6) = .0417$. Again, since $.0490 > .0417$, the procedure would continue by comparing $p_4 = .0145$ to $\alpha(c/C) = .05(4/6) = .0333$. Since $.0145 < .0333$, H_4 would be rejected. Because at least one H_c was rejected during the first stage, testing continues by estimating each of the slopes, $S_c = (1 - p_c)/(C - c + 1)$, for $c = 1, \dots, C$. The calculated slopes for this example are: $S_1 = .1664$, $S_2 = .1991$, $S_3 = .2475$, $S_4 = .3285$, $S_5 = .4755$ and $S_6 = .8761$. Given that all $S_c > S_{c-1}$, S^* is set at $C = 6$. The estimated number of true nulls is then determined by $\hat{C}_T = \min[(1/S^*) + 1, C] = \min[(1/6) + 1, 6] = \min[1.1667, 6] = 1$. Therefore, the BH-A procedure would compare $p_6 = .1239$ to $\alpha(c/\hat{C}_T) = .05(6/1) = .30$. Since $.1239 < .30$, but $.1239 > \alpha$, H_6 would not be rejected and the procedure would continue by comparing $p_5 = .0490$ to $\alpha(c/\hat{C}_T) = .05(5/1) = .25$. Since $.0490 < .25$ and $.0490 < \alpha$, H_5 would be rejected; in addition, all $H_{c'}$ would also be rejected (i.e., H_1, H_2, H_3 , and H_4).

Stepwise MCPs Based on the Closure Principle. As we indicated previously, researchers can adopt stepwise procedures when examining all possible pairwise comparisons, and typically they provide greater sensitivity to detect differences than do STPs, for example, Tukey's [60] method, while still maintaining strong FWE control. In this section, we present some methods related to closed-testing sequential MCPs that can be obtained through the SAS system of programs.

As Westfall et al. [65, p. 150] note, it was in the past two decades (from their 1999 publication) that a unified approach to stepwise testing has evolved.

The unifying concept has been the closure principle. MCPs based on this principle have been designated as closed-testing procedures. These methods are designated as closed-testing procedures because they address families of hypotheses that are closed under intersection ($\cap$). By definition, a closed family 'is one for which any subset intersection hypothesis involving members of the family of tests is also a member of the family'.

The closed-testing principle has led to a way of performing multiple tests of significance such that FWE is strongly controlled with results that are coherent. A coherent MCP is one that avoids inconsistencies in that it will not reject a hypothesis without rejecting all hypotheses implying it (see [20], pp. 44–45). Because closed-testing procedures were not always easy to derive, various authors derived other simplified stepwise procedures which are computationally simpler, though at the expense of providing smaller α values than what theoretically could be obtained with a closed-testing procedure. Naturally, as a consequence of having smaller α values (Type I errors are too tightly controlled), these simpler stepwise MCPs would not be as powerful as exact closed-testing methods. Nonetheless, these methods are still typically more powerful than STPs (e.g., Tukey) and therefore are recommended and furthermore, researchers can obtain numerical results through the SAS system.

REGWQ. One such method was introduced by Ryan [49], Einot and Gabriel [11] and Welsch [64] and is available through SAS. One can better understand the logic of the REGWQ procedure if we first introduce one of the most popular stepwise strategies for examining pairwise differences between means, the Newman-Keuls (NK) procedure.

In this procedure, the means are rank ordered from smallest to largest and the difference between the smallest and largest means is first subjected to a statistical test, typically with a range statistic (Q), at an α level of significance. If this difference is not significant, testing stops and all pairwise differences are regarded as null. If, on the other hand, this first range test is statistically significant, one 'steps-down' to examine the two $J - 1$ subsets of ordered means, that is, the smallest mean versus the next-to-largest mean and the largest mean versus the next-to-smallest mean, with each tested at an α level of significance. At each stage of testing, only subsets of ordered

means that are statistically significant are subjected to further testing. Although the NK procedure is very popular among applied researchers, it is becoming increasingly well known that when $J > 3$ it does not limit the FWE to α (see [20], p. 69).

Ryan [49] and Welsch [64], however, have shown how to adjust the subset levels of significance in order to provide strong FWE control. Specifically, in order to strongly control FWE a researcher must:

- Test all subset ($p = 2, \dots, J$) hypotheses at $\alpha_p = 1 - (1 - \alpha)^{\frac{p}{J}}$, for $p = 2, \dots, J - 2$ and at level $\alpha_p = \alpha$ for $p = J - 1, J$.
- Testing starts with an examination of the complete null hypothesis $\mu_1 = \mu_2 = \dots = \mu_J$, and if rejected one steps down to examine subsets of $J - 1$ means, $J - 2$ means, and so on.
- All subset hypotheses implied by a homogeneity hypothesis that has not been rejected are accepted as null without testing.

REGWQ can be implemented with the SAS GLM program. We remind the reader, however, that this procedure cannot be used to construct simultaneous confidence intervals.

MCPs that Allow Variances to be Heterogeneous

The previously presented procedures assume that the population variances are equal across treatment conditions. Given available knowledge about the non-robustness of MCPs with conventional test statistics (e.g., t , F), and evidence that population variances are commonly unequal (see [28], [67]), researchers who persist in applying MCPs with conventional test statistics increase the risk of Type I errors. As Olejnik and Lee [43, p. 14] conclude, 'most applied researchers are unaware of the problem [of using conventional test statistics with heterogeneous variances (see **Heteroscedasticity and Complex Variation**) and probably are unaware of the alternative solutions when variances differ'.

Although recommendations in the literature have focused on the Games–Howell [14], or Dunnett [10] procedures for designs with unequal σ_j^2 s (e.g., see [34], [59]), sequential procedures can provide more power than STPs while generally controlling the FWE (see [24], [36]).

8 Multiple Comparison Procedures

The SAS software can once again be used to obtain numerical results. In particular, Westfall et al. [65, pp. 206–207] provide SAS programs for logically constrained step-down pairwise tests when heteroscedasticity exists. The macro uses SASs mixed-model program (PROC MIXED), which allows for a nonconstant error structure across groups. As well, the program adopts the Satterthwaite [53] solution for error df. Westfall et al. remind the reader that the solution requires large data sets in order to provide approximately correct FWE control.

It is important to note that other non-SAS solutions are possible in the heteroscedastic case. For completeness, we note how these can be obtained. Specifically, sequential procedures based on the usual t_c statistic can be easily modified for unequal σ_j^2 s (and unequal n_j s) by substituting Welch's [62] statistic, $t_w(v_w)$ for $t_c(v)$, where

$$t_w = \frac{\bar{Y}_j - \bar{Y}_{j'}}{\sqrt{\frac{s_j^2}{n_j} + \frac{s_{j'}^2}{n_{j'}}}}, \quad (10)$$

and s_j^2 and $s_{j'}^2$ represent the sample variances for the j th and j' th group, respectively. This statistic is approximated as a t variate with critical value $t_{(1-\alpha/2, v_w)}$, the $100(1 - \alpha/2)$ quantile of Student's t distribution with df

$$v_w = \frac{\left\{ \frac{s_j^2}{n_j} + \frac{s_{j'}^2}{n_{j'}} \right\}^2}{\frac{(s_j^2/n_j)^2}{n_j - 1} + \frac{(s_{j'}^2/n_{j'})^2}{n_{j'} - 1}}. \quad (11)$$

For procedures, simultaneously comparing more than two means or when an omnibus test statistic is required (protected tests), robust alternatives to the usual **analysis of variance** (ANOVA) F statistic have been suggested. Possibly the best-known robust omnibus test is that due to Welch [63]. With the Welch procedure, the omnibus null hypothesis is rejected if $F_w > F_{(J-1, v_w)}$ where:

$$F_w = \frac{\sum_{j=1}^J w_j (\bar{Y}_j - \tilde{Y})^2 / (J - 1)}{1 + \frac{2(J - 2)}{(J^2 - 1)} \sum_{j=1}^J \frac{(1 - w_j / \Sigma w_j)^2}{n_j - 1}}, \quad (12)$$

$w_j = n_j / s_j^2$, and $\tilde{Y} = \Sigma w_j \bar{Y}_j / \Sigma w_j$. The statistic is approximately distributed as an F variate and

is referred to the critical value, $F_{(1-\alpha, J-1, v_w)}$, the $100(1 - \alpha)$ quantile of the F distribution with $J - 1$ and v_w df, where

$$v_w = \frac{J^2 - 1}{3 \sum_{j=1}^J \frac{(1 - w_j / \Sigma w_j)^2}{n_j - 1}}. \quad (13)$$

The Welch test has been found to be robust for largest to smallest variance ratios less than 10:1 (Wilcox, Charlin & Thompson [71]).

On the basis of the preceding, one can use the nonpooled Welch test and its accompanying df to obtain various stepwise MCPs. For example, Keselman et al. [27] verified that one can use this approach with Hochberg's [19] step-up Bonferroni MCP (see Westfall et al. [65], pp. 32–33) as well as with Benjamini and Hochberg's [2] FDR method to conduct all possible pairwise comparisons in the heteroscedastic case.

MCPs That Can be Used When Data are Nonnormal

An underlying assumption of all of the previously presented MCPs is that the populations from which the data are sampled are normally distributed; this assumption, however, may rarely be accurate (see [39], [44], [68]) (Tukey [61] suggests that most populations are skewed and/or contain outliers). Researchers falsely assuming normally distributed data risk obtaining biased Type I and/or Type II error rates for many patterns of nonnormality, especially when other assumptions are also not satisfied (e.g., variance homogeneity) (see [70]).

Bootstrap and Permutation Tests. The SAS system allows users to obtain both simultaneous and stepwise pairwise comparisons of means with methods that do not presume normally distributed data. In particular, users can use either **bootstrap** or **permutation** methods to compute all possible pairwise comparisons.

Bootstrapping allows users to create their own empirical distribution of the data and hence P values are accordingly based on the empirically obtained distribution, not a theoretically presumed distribution. For example, the empirical distribution, say $\hat{F}$, is obtained by sampling, *with replacement*, the pooled

sample residuals $\hat{\epsilon}_{ij} = Y_{ij} - \hat{\mu}_j = Y_{ij} - \bar{Y}_j$. That is, rather than assume that residuals are normally distributed, one uses empirically generated residuals to estimate the true shape of the distribution. From the pooled sample residuals one generates bootstrap data.

An example program for all possible pairwise comparisons is given by Westfall et al. [65, p. 229].

As well, pairwise comparisons of means (or ranks) can be obtained through permutation of the data with the program provided by Westfall et al. [65, pp. 233–234]. Permutation tests also do not require that the data be normally distributed. Instead of resampling with replacement from a pooled sample of residuals, permutation tests take the observed data $(Y_{11}, \dots, Y_{n1}, \dots, Y_{1J}, \dots, Y_{nJ})$ and randomly redistributes them to the treatment groups, and summary statistics (i.e., means or ranks) are then computed on the randomly redistributed data. The original outcomes (all possible pairwise differences from the original sample means) are then compared to the randomly generated values (e.g., all possible pairwise differences in the permutation samples).

When users adopt this approach to combat the effects of nonnormality they should take heed of the cautionary note provided by Westfall et al. [65, p. 234], namely, the procedure may not control the FWE when the data have heterogeneous variances, particularly when group sizes are unequal. Thus, we introduce another approach, pairwise comparisons based on robust estimators and a heteroscedastic statistic, an approach that has been demonstrated to generally control the FWE when data are non-normal and heterogeneous even when group sizes are unequal.

MCPs That Can be Used When Data are Neither Normal Nor When Variances are Heterogeneous

Trimmed Means Approach. A different type of testing procedure, based on trimmed (or censored) means (*see Trimmed Means*), has been discussed by Yuen and Dixon [73] and Wilcox [69, 70], and is purportedly robust to violations of normality.

That is, it is well known that the usual group means and variances, which are the bases for all of the previously described procedures, are greatly influenced by the presence of extreme observations

in distributions. In particular, the standard error of the usual mean can become seriously inflated when the underlying distribution has heavy tails. Accordingly, adopting a nonrobust measure ‘can give a distorted view of how the typical individual in one group compares to the typical individual in another, and about accurate probability coverage, controlling the probability of a Type I error, and achieving relatively high power’ [69, p. 66]. By substituting robust measures of location and scale for the usual mean and variance, it should be possible to obtain test statistics that are insensitive to the combined effects of variance heterogeneity and nonnormality.

While a wide range of robust estimators have been proposed in the literature (*see [15]*), the trimmed mean and Winsorized variance (*see Winsorized Robust Measures*) are intuitively appealing because of their computational simplicity and good theoretical properties [69]. The standard error of the trimmed mean is less affected by departures from normality than the usual standard error mean because extreme observations, that is, observations in the tails of a distribution, are censored or removed.

Trimmed means are computed by removing a percentage of observations from each of the tails of a distribution (set of observations). Let $Y_{(1)} \leq Y_{(2)} \leq \dots \leq Y_{(n)}$ represent the ordered observations associated with a group. Let $g = [\gamma n]$, where γ represents the proportion of observations that are to be trimmed in each tail of the distribution and $[x]$ is notation for the largest integer not exceeding x . Wilcox [69] suggests that 20% trimming should be used. The effective sample size becomes $h = n - 2g$. Then the sample trimmed mean is

$$\bar{Y}_t = \frac{1}{h} \sum_{i=g+1}^{n-g} Y_{(i)}. \quad (14)$$

An estimate of the standard error of the trimmed mean is based on the Winsorized mean and Winsorized sum of squares (*see Winsorized Robust Measures*). The sample Winsorized mean is

$$\begin{aligned} \bar{Y}_w = \frac{1}{n} [& (g+1)Y_{(g+1)} + Y_{(g+2)} + \dots + Y_{(n-g-1)} \\ & + (g+1)Y_{(n-g)}], \end{aligned} \quad (15)$$

and the sample Winsorized sum of squared deviations is

$$SSD_w = (g+1)(Y_{(g+1)} - \bar{Y}_w)^2$$

$$\begin{aligned}
& + (Y_{(g+2)} - \bar{Y}_w)^2 + \cdots + (Y_{(n-g-1)} - \bar{Y}_w)^2 \\
& + (g+1)(Y_{(n-g)} - \bar{Y}_w)^2.
\end{aligned} \quad (16)$$

Accordingly, the sample Winsorized variance is $\hat{\sigma}_w^2 = SSD_w/(n-1)$ and the squared standard error of the mean is estimated as [58]

$$d = \frac{(n-1)\hat{\sigma}_w^2}{h(h-1)}. \quad (17)$$

To test a pairwise comparison null hypothesis, compute $\bar{Y}_t$ and d for the j th group, label the results $\bar{Y}_{tj}$ and d_j . The robust pairwise test (see Keselman, Lix & Kowalchuk [31]) becomes

$$t_w = \frac{\bar{Y}_{tj} - \bar{Y}_{tj'}}{\sqrt{d_j + d_{j'}}}, \quad (18)$$

with estimated df

$$v_w = \frac{(d_j + d_{j'})^2}{d_j^2/(h_j - 1) + d_{j'}^2/(h_{j'} - 1)}. \quad (19)$$

When trimmed means are being compared, the null hypothesis relates to the equality of population-trimmed means, instead of population means. Therefore, instead of testing $H_0: \mu_j = \mu_{j'}$, a researcher would test the null hypothesis, $H_0: \mu_{tj} = \mu_{tj'}$, where μ_t represents the population-trimmed mean (Many researchers subscribe to the position that inferences pertaining to robust parameters are more valid than inferences pertaining to the usual least squares parameters, when they are dealing with populations that are nonnormal in form.

Yuen and Dixon [73] and Wilcox [69] report that for long-tailed distributions, tests based on trimmed means and Winsorized variances can be much more powerful than tests based on the usual mean and variance. Accordingly, when researchers feel they are dealing with nonnormal data, they can replace the usual least squares estimators of central tendency and variability with robust estimators and apply these estimators in any of the previously recommended MCPs.

A Model Testing Procedure. The procedure to be described takes a completely different approach to specifying differences between the treatment group means. That is, unlike previous approaches which rely on a test statistic to reject or accept pairwise null hypotheses, the approach to be described uses an information criterion statistic to select a configuration

of population means which most likely corresponds with the observed data. Thus, as Dayton [6, p. 145] notes, ‘model-selection techniques are not statistical tests for which type I error control is an issue.’

When testing all pairwise comparisons, intransitive decisions are extremely common with conventional MCPs [6]. An intransitive decision refers to declaring a population mean (μ_j) not significantly different from two different population means ($\mu_j = \mu_{j'}$, $\mu_j = \mu_{j''}$), when the latter two means are declared significantly different ($\mu_{j'} \neq \mu_{j''}$). For example, a researcher conducting all pairwise comparisons ($J = 4$) may decide not to reject any hypotheses implied by $\mu_1 = \mu_2 = \mu_3$ or $\mu_3 = \mu_4$, but reject $\mu_1 = \mu_4$ and $\mu_2 = \mu_4$, based on results from a conventional MCP. Interpreting the results of this experiment can be ambiguous, especially concerning the outcome for μ_3 .

Dayton [6] proposed a model testing approach based on **Akaike’s Information Criterion (AIC)** [1]. Mutually exclusive and transitive models are each evaluated using AIC, and the model having the minimum AIC is retained as the most probable population mean configuration, where:

$$AIC = SS_w + \sum_j n_j (\bar{Y}_j - \bar{Y}_{mj})^2 + 2q, \quad (20)$$

$\bar{Y}_{mj}$ is the estimated sample mean for the j th group (given the hypothesized population mean configuration for the m th model), SS_w is the ANOVA pooled within group sum of squares and q is the degree of freedom for the model. For example, for $J = 4$ (with ordered means) there would be $2^{J-1} = 8$ different models to be evaluated ($\{1234\}$, $\{1, 234\}$, $\{12, 34\}$, $\{123, 4\}$, $\{1, 2, 34\}$, $\{12, 3, 4\}$, $\{1, 23, 4\}$, $\{1, 2, 3, 4\}$). To illustrate, the model $\{12, 3, 4\}$ postulates a population mean configuration where groups one and two are derived from the same population, while groups three and four each represent independent populations. The model having the lowest AIC value would be retained as the most probable population model.

Dayton’s AIC model-testing approach has the virtue of avoiding intransitive decisions. It is more powerful in the sense of all-pairs power than Tukey’s MCP, which is not designed to avoid intransitive decisions. One finding reported by Dayton, as well as Huang and Dayton [25], is that the AIC has a slight bias for selecting more complicated models than the true model. For example, Dayton found

that for the mean pattern $\{12, 3, 4\}$, AIC selected the more complicated pattern $\{1, 2, 3, 4\}$ more than ten percent of the time, whereas AIC only rarely selected less complicated models (e.g., $\{12, 34\}$). This tendency can present a special problem for the complete null case $\{1234\}$, where AIC has a tendency to select more complicated models. Consequently, a recommendation by Huang and Dayton [25] is to use an omnibus test to screen for the null case, and then assuming rejection of the null, apply the Dayton procedure.

Dayton's [6] model testing approach can be modified to handle heterogeneous treatment group variances. Like the original procedure, mutually exclusive and transitive models are each evaluated using AIC, and the model having the minimum AIC is retained as the most probable population mean configuration. For heterogeneous variances:

$$\text{AIC} = -2 \left\{ \left(\frac{-N}{2} \right) (\ln(2\pi) + 1) - \frac{1}{2} (\sum n_j \ln(S)) \right\} + 2q, \quad (21)$$

where S is the biased variance for the j th group, substituting the estimated group mean (given the hypothesized mean configuration for the m th model) for the actual group mean in the calculation of the variance. As in the original Dayton procedure, an appropriate omnibus test can also be applied.

Complex Comparisons

To introduce some methods that can be adopted when investigating complex comparisons among treatment group means, we first expand on our introductory definitions. Specifically, we let

$$\psi = c_1\mu_1 + c_2\mu_2 + \cdots + c_J\mu_J, \quad (22)$$

(where the coefficients (c_j s) defining the contrast sum to one (i.e., $\sum_{j=1}^J c_j = 0$)) represent the population complex contrast that we are interested in subjecting to a test of significance. To test that $H_0: \psi = 0$, we replace the unknown population values with their **least squares estimates**, that is, the sample means, and subject the sample contrast estimate

$$\hat{\psi} = c_1\bar{Y}_1 + c_2\bar{Y}_2 + \cdots + c_J\bar{Y}_J \quad (23)$$

to a test with the statistic

$$t_{\hat{\psi}} = \frac{\hat{\psi}}{\sqrt{\text{MSE} \sum_{j=1}^J c_j^2/n_j}}. \quad (24)$$

As we indicated in the beginning of our paper, a very popular method for examining complex contrasts is Scheffé's [55] method. Scheffé's method, as we indicated, is an STP method that provides FWE control, that is, a procedure that uses one critical value to assess statistical significance of a set of complex comparisons. The simultaneous critical value is

$$\sqrt{(J-1)F_{1-\alpha, J-1, v}}, \quad (25)$$

where $F_{1-\alpha, J-1, v}$ is the $1-\alpha$ quantile from the sampling distribution of F based on $J-1$ and v numerator and denominator degrees of freedom (numerator and denominator df that are associated with the omnibus ANOVA F test). Accordingly, one rejects the hypothesis H_0 when

$$t_{\hat{\psi}} \geq \sqrt{(J-1)F_{1-\alpha, J-1, v}}. \quad (26)$$

Bonferroni. Another very popular STP method for evaluating a set of m complex comparisons is to compare the P values associated with the $t_{\hat{\psi}}$ statistics to the Dunn-Bonferroni critical value α/m or one may refer $|t_{\hat{\psi}}|$ to their simultaneous critical value (see Kirk [34], p. 829 for the table of critical values). As has been pointed out, researchers can compare, *a priori*, the Scheffé [55] and Dunn-Bonferroni critical values, choosing the smaller of the two, in order to obtain the more powerful of the two STPs. That is, the statistical procedure with the smaller critical value will provide more statistical power to detect true complex comparison differences between the means. In general though, if there are 20 or fewer comparisons, the Dunn-Bonferroni method will provide the smaller critical value and hence the more powerful approach with the reverse being the case, when there are more than 20 comparisons [65, p. 117].

One may also adopt stepwise MCPs when examining a set of m complex comparisons. These stepwise methods should result in greater sensitivity to detect effects than the Dunn-Bonferroni method. Many others have devised stepwise Bonferroni-type MCPs, for example, Holm [23], Holland and Copenhaver [22],

12 Multiple Comparison Procedures

Hochberg [19], Rom [46], and so on. All of these procedures provide FWE control; the minor differences between them can result in small differences in power to detect effects. Thus, we recommend the Hochberg [19] sequentially acceptable step-up Bonferroni procedure previously described because it is simple to understand and implement.

Finally, we note that the Scheffé [55], Dunn-Bonferroni [9] and Hochberg [19] procedures can be adopted to robust estimation and testing by adopting trimmed means and Winsorized variances, instead of the usual least squares estimators. That is, to circumvent the biasing effects of nonnormality and variance heterogeneity, researchers can adopt a heteroscedastic Welch-type statistic and its accompanying modified degrees of freedom, applying robust estimators. For example, the heteroscedastic test statistic for the Dunn-Bonferroni [9] and Hochberg [19] procedures would be

$$t_{\hat{\psi}} = \frac{\hat{\psi}}{\sqrt{\sum_{j=1}^J c_j^2 s_j^2 / n_j}}, \quad (27)$$

where the statistic is approximately distributed as a Student t variable with

$$df_w = \frac{\left(\sum_{j=1}^J c_j^2 s_j^2 / n_j \right)^2}{\sum_{j=1}^J [(c_j^2 s_j^2 / n_j)^2 / (n_j - 1)]}. \quad (28)$$

Accordingly, as we specified previously, one replaces the least squares means with trimmed means and least squares variances with variances based on Winsorized sums of squares. That is,

$$t_{\hat{\psi}_t} = \frac{\hat{\psi}_t}{\sqrt{\sum_{j=1}^J c_j^2 d_j}}, \quad (29)$$

where the sample comparison of trimmed means equals

$$\hat{\psi}_t = c_1 \bar{Y}_{t1} + c_2 \bar{Y}_{t2} + \cdots + c_J \bar{Y}_{tJ} \quad (30)$$

and error degrees of freedom is given by

$$df_{wt} = \frac{\left(\sum_{j=1}^J c_j^2 d_j \right)^2}{\sum_{j=1}^J [(c_j^2 d_j)^2 / (h_j - 1)]}. \quad (31)$$

A robust Scheffé [55] procedure would be similarly implemented, however, one would use the heteroscedastic Brown and Forsythe [5] statistic (see Kirk [34], p. 155). It is important to note that, although we are unaware of any empirical investigations that have examined tests of complex contrasts with robust estimators, based on empirical investigations related to pairwise comparisons, we believe these methods would provide approximate FWE control under conditions of nonnormality and variance heterogeneity and should possess more power to detect group differences than procedures based on least squares estimators.

Extensions

We have presented newer MCPs within the context of a one-way completely randomized design, highlighting procedures that should be robust to variance heterogeneity and nonnormality. We presented these methods because we concur with others that behavioral science data will not likely conform to these derivational requirements, assumptions which were adopted to derive the classical procedures, for example, [60] and [55]. For completeness, we note that robust procedures, that is, MCPs (omnibus tests as well) that employ a heteroscedastic test statistic and adopt robust estimators rather than the usual least squares estimators for the mean and variance, have also been enumerated within the context of factorial between-subjects and factorial between- by within-subjects repeated measures designs. Accordingly, applied researchers can note the generalization of the methods presented in our paper, to those that have been presented within these more general contexts by Keselman and Lix [30], Lix and Keselman [38], Keselman [26] and Keselman, Wilcox and Lix [32].

Numerical Example

We present a numerical example for the previously discussed MCPs so that the reader can check his/her facility to work with the SAS/Westfall et al. [65] programs and to demonstrate through example the differences between their operating characteristics. (Readers can obtain a copy of the SAS [52] and SPSS [42] syntax that we used to obtain numerical results from the third author.) In particular, the data ($n_1 = n_2 = \dots = n_J = 20$) presented in Table 1 were randomly generated by us though they could represent the outcomes of a problem solving task where the five groups were given different clues to solve the problem; the dependent measure was the time, in seconds, that it took to solve the task. The bottom two rows of the table contain the group means and standard deviations, respectively.

Table 2 contains FWE ($\alpha = .05$) significant (*) comparisons for the 10 pairwise comparisons for the five groups. The results reported in Table 2 generally conform, not surprisingly, to the properties of the MCPs that we discussed previously. In particular, of the ten comparisons, four were found to be statistically significant with the Tukey [60] procedure:

Note: TK-Tukey (1953); HY-Hayter (1986); HC-Hochberg (1988); SH-Shaffer (1979); BT-(Bootstrap)/PM (Permutation)-Westfall et al.; BH-Benjamini & Hochberg (1995); BH-A(Adaptive)-Benjamini & Hochberg (2002); RG-Ryan (1960)-Einot & Gabriel (1975)-Welsch (1977); TM-Trimmed means (and Winsorized variances) used with a nonpooled t Test and BH critical constants. Raw P values (1 vs 2, ..., 4 vs 5) for the SAS (1999) procedures are .1406, .0007, .0002, < .0001, .0469, .0185, < .0001, .7022, .0065 and .0185. The corresponding values for the trimmed means tests are .0352, .0102, .0001, .0003, .1428, .0076, .0044, .6507, .1271 and .1660.

$\mu_1 - \mu_3$, $\mu_1 - \mu_4$, $\mu_1 - \mu_5$, and $\mu_2 - \mu_5$. In addition to these four comparisons, the Hayter [18], Hochberg [19], Shaffer [57], bootstrap [see 65] and permutation [see 65] MCPs found one additional comparison ($\mu_3 - \mu_5$) to be statistically significant. The REGWQ procedure also identified these comparisons as significant plus one additional one- $\mu_4 - \mu_5$. The BH [2] and BH-A [3] MCPs detected these contrasts as well, plus one and two others, respectively. In particular, BH and BH-A also identified $\mu_2 - \mu_4$ as significant, while BH-A additionally declared $\mu_2 - \mu_3$ significant. Thus, out of the ten comparisons, BH-A declared eight to be statistically significant. Clearly the procedures based on the more liberal FDR found more comparisons to be statistically significant than the FWE controlling MCPs. (Numerical results for BH-A were not obtained through SAS; they were obtained through hand-calculations.)

We also investigated the ten pairwise comparisons with the trimmed means and model-testing procedures; the results for the trimmed means analysis are also reported in Table 2. In particular, we computed the group trimmed means ($\bar{Y}_{t1} = 14.92$, $\bar{Y}_{t2} = 16.67$, $\bar{Y}_{t3} = 18.50$, $\bar{Y}_{t4} = 19.08$ and $\bar{Y}_{t5} = 21.08$) as well as the group Winsorized variances ($\hat{\sigma}_{W1}^2 = 2.58$, $\hat{\sigma}_{W2}^2 = 1.62$, $\hat{\sigma}_{W3}^2 = 8.16$, $\hat{\sigma}_{W4}^2 = 3.00$ and $\hat{\sigma}_{W5}^2 =$

= 10.26). These values can be obtained with the SAS/IML program discussed by Keselman et al. [32] or one can create a ‘special’ SPSS [42] data set to calculate nonpooled t statistics (t_W and v_W) and their corresponding P values (through the ONEWAY program) (These programs can be obtained from the first author). The results reported in Table 2 indicate that with this approach five comparisons were found to be statistically significant: $\mu_1 - \mu_3$, $\mu_1 - \mu_4$, $\mu_1 - \mu_5$, $\mu_2 - \mu_4$, and $\mu_2 - \mu_5$. Clearly, other MCPs had greater power to detect more pairwise differences. However, the reader should remember that robust estimation should result in more powerful tests when data are nonnormal as well as heterogeneous (see Wilcox [70]), which was not the case with our numerical example data. Furthermore, trimmed results were based on 12 subjects per group, not 20.

With regard to the model-testing approach, we examined the 2^{J-1} models of nonoverlapping subsets of ordered means and used the minimum AIC value to find the best model that ‘is expected to result in the smallest loss of precision relative to the true, but unknown, model (Dayton [6], p. 145).’ From the 16 models examined, the two models with the smallest AIC values were $\{1, 2, 34, 5\}$ ($AIC = 527.5$) and $\{12, 34, 5\}$ ($AIC = 527.8$). The ‘winning’ model combines one pair but clearly there is another model that is plausible given the data available. (Results were obtained through hand calculations. However, a GAUSS program is available from the Department of Measurement & Statistics, University of Maryland web site.) Though this ambiguity might

seem like a negative feature of the model-testing approach, Dayton [6] would maintain that being able to enumerate a set of conclusions (i.e., competing models) provides a broader more comprehensive perspective regarding group differences than does the traditional approach.

We also computed a set of complex contrasts (nine) among the five treatment group means to allow the reader to check his/her understanding of the computational operations associated with the MCPs that can be used when examining a set of complex contrasts. The population contrasts examined, their sample values, and the decisions regarding statistical significance ($FWE = .05$) are enumerated in Table 3. Again results conform to the operating characteristics of the MCPs. In particular, the Scheffé [55] procedure found the fewest number of significant contrasts, Hochberg’s [19] step-up Bonferroni procedure the most, and the number found to be significant according to the Dunn–Bonferroni [55] criterion was intermediate to Scheffé [55] and Hochberg [19]. When applying Hochberg’s [19] MCP with trimmed means and Winsorized variances six of the nine complex contrasts were found to be statistically significant.

Multiple Comparison Tests: Nonparametric and Resampling Approaches

Introduction

An underlying assumption of classical **multiple comparison procedures (MCPs)** is that the populations from which the data are sampled are normally distributed. Additional assumptions are that the population variances are equal (the homogeneity of variances assumption) and that the errors or observations are independent from one another (the independence of observations assumption). Although it may be convenient (both practically and statistically) for researchers to assume that their samples are obtained from normally distributed populations, this assumption may rarely be accurate [21, 31]. Researchers falsely assuming normally distributed data risk obtaining biased tests and relatively high Type II error rates for many patterns of nonnormality, especially when other assumptions are also not satisfied (e.g., variance homogeneity) (See [31]). Inaccurate **confidence intervals** occur as well.

The assumptions associated with the classical test statistics are typically associated with the following mathematical model that describes the sources that contribute to the magnitude of the dependent scores. Specifically, a mathematical model that can be adopted when examining pairwise and/or complex comparisons of means in a one-way completely randomized design is:

$$Y_{ij} = \mu_j + \epsilon_{ij}, \quad (1)$$

where Y_{ij} is the score of the i th subject ($i = 1, \dots, n_j$) in the j th ($j = 1, \dots, J$) group, $\sum_j n_j = N$, μ_j is the j th group mean, and ϵ_{ij} is the random error for the i th subject in the j th group. As indicated, in the typical application of the model, it is assumed that the ϵ_{ij} s are normally and independently distributed and that the treatment group variances (σ_j^2 s) are equal. Relevant sample estimates include

$$\hat{\mu}_j = \bar{Y}_j = \sum_{i=1}^{n_j} \frac{Y_{ij}}{n_j} \text{ and } \hat{\sigma}^2 = \text{MSE}$$

$$= \frac{\sum_{j=1}^J \sum_{i=1}^{n_j} (Y_{ij} - \bar{Y}_j)^2}{\sum_{j=1}^J (n_j - 1)}. \quad (2)$$

Pairwise Comparisons

A confidence interval, assuming equal sample sizes n , for convenience, for a pairwise difference $\mu_j - \mu_{j'}$ has the form

$$\bar{Y}_j - \bar{Y}_{j'} \pm c_\alpha \hat{\sigma} \sqrt{\frac{2}{n_j}},$$

where c_α is selected such that the overall rate of Type I error (the probability of making at least one Type I error in the set of say m tests), that is, the familywise rate of Type I error (FWE) $= \alpha$. In the case of all possible pairwise comparisons, one needs a c_α such that the simultaneous probability coverage achieves a specified level. That is, for all $j \neq j'$, c_α must satisfy

$$P \left(\bar{Y}_j - \bar{Y}_{j'} - c_\alpha \hat{\sigma} \sqrt{\frac{2}{n_j}} \leq \mu_j - \mu_{j'} \leq \bar{Y}_j - \bar{Y}_{j'} + c_\alpha \hat{\sigma} \sqrt{\frac{2}{n_j}} \right) = 1 - \alpha. \quad (3)$$

Resampling Methods

Researchers can use both simultaneous and stepwise MCPs for pairwise comparisons of means with methods that do not assume normally distributed data. (Simultaneous MCPs use one critical value to assess statistical significance while stepwise procedures use a succession of critical value to assess statistical significance.) In particular, users can use either **permutation** or **bootstrap** methods to compute all possible pairwise comparisons, leading to hypothesis tests of such comparisons.

Pairwise comparisons of groups can be obtained through permutation of the data with the program provided by Westfall et al. [28, pp. 233–234]. Permutation tests do not require that the data be normally distributed. Instead of resampling with replacement from a pooled sample of residuals, permutation tests take the observed data ($Y_{11}, \dots, Y_{n11}, \dots, Y_{1J}, \dots, Y_{nJJ}$)

2 Multiple Comparison Tests

and randomly redistributes them to the treatment groups, and summary statistics (i.e., means or ranks) are then computed on the randomly redistributed data. The original outcomes (all possible pairwise differences from the original sample means) are then compared to the randomly generated values (e.g., all possible pairwise differences in the permutation samples). See [22] and [26].

Permutation tests can be used with virtually any measure of location, but regardless of which measure of location is used, they are designed to test the hypothesis that groups have identical distributions (e.g., [23]). If, for example, a permutation test based on means is used, it is not robust (*see Robust Testing Procedures*) if the goal is to make inferences about means (e.g., [1]).

When users adopt this approach to combat the effects of nonnormality, they should also heed the cautionary note provided by Westfall et al. [28, p. 234], namely, the procedure may not control the FWE when the data are heterogeneous, particularly when group sizes are unequal. Thus, we will introduce another approach, pairwise comparisons based on robust estimators and a heteroscedastic statistic, an approach that has been demonstrated to generally control the FWE when data are nonnormal and heterogeneous even when group sizes are unequal.

Prior to introducing bootstrapping with robust estimators it is important to note for completeness that researchers also can adopt nonparametric methods (*see Distribution-free Inference, an Overview*) to examine pairwise and/or complex contrasts among treatment group means (see e.g., [8] and [11]). However, one should remember that this approach is only equivalent to the classical approach of comparing treatment group means (comparing the same full and restricted models) when the distributions that are being compared are equivalent except for possible differences in location (i.e., a shift in location). That is, the classical and nonparametric approaches test the same hypothesis when the assumptions of the shift model hold; otherwise, the nonparametric approach is not testing merely for a shift in location parameters of the J groups (see [20], [4]).

Generally, conventional nonparametric tests are not aimed at making inferences about means or some measure of location. For example, the **Wilcoxon–Mann–Whitney test** is based on an estimate of $p(X < Y)$, the probability that an observation from the first group is less

than an observation from the second (e.g., see [3]). If restrictive assumptions are made about the distributions being compared, conventional nonparametric tests have implications about measures of location [6], but there are general conditions where a more accurate description is that they test the hypothesis of *identical distributions*. Interesting exceptions are given by Brunner, Domhof, and Langer [2] and Cliff [3]. For those researchers who believe nonparametric methods are appropriate (e.g., Kruskal–Wallis), we refer the reader to [8], [11], [20], or [25].

Robust Estimation

Bootstrapping methods provide an estimate of the distribution of the test statistic yielding P values that are not based on a theoretically presumed distribution (see e.g., [19]; [29]). An example SAS [22] program for all possible pairwise comparisons (of least squares means) is given by Westfall et al. [28, p. 229].

Westfall and Young's [29] results suggest that Type I error control could be improved further by combining a bootstrap method with one based on trimmed means. When researchers feel that they are dealing with populations that are nonnormal in form and thus subscribe to the position that inferences pertaining to robust parameters are more valid than inferences pertaining to the usual least squares parameters, then procedures, based on robust estimators, say trimmed means, should be adopted. Wilcox et al. [30] provide empirical support for the use of robust estimators and test statistics with bootstrap-determined critical values in one-way independent groups designs. This benefit has also been demonstrated in correlated groups designs (see [14]; [15]).

Accordingly, researchers can apply robust estimates of central tendency and variability to a heteroscedastic test statistic (*see Heteroscedasticity and Complex Variation*) (e.g., Welch's test [27]; also see [16]). When trimmed means are being compared the multiple comparison null hypothesis pertains to the equality of population trimmed means, that is, $H_0: \psi = \mu_{tj} - \mu_{tj'} = 0 (j \neq j')$. Although the null hypothesis stipulates that the population trimmed means are equal, we believe this is a reasonable hypothesis to examine since trimmed means, as opposed to the usual (least squares) means, provide better estimates of the typical individual in distributions that either contain **outliers** or are skewed. That

is, when distributions are skewed, trimmed means do not estimate μ but rather some value (i.e., μ_t) that is typically *closer* to the bulk of the observations. (Another way of conceptualizing the unknown parameter μ_t is that it is simply the population counterpart of $\hat{\mu}_t$ (see [12] and [9]). And lastly, as Zhou, Gao, and Hui [34] point out, distributions are typically skewed.

Thus, with robust estimation, the trimmed group means ($\hat{\mu}_{tj}$ s) replace the least squares group means ($\hat{\mu}_j$ s), the Winsorized group variances estimators (see **Winsorized Robust Measures**) ($\hat{\sigma}_{wj}^2$ s) replace the least squares variances ($\hat{\sigma}_j^2$ s), and h_j replaces n_j and accordingly one computes the robust version of a heteroscedastic test statistic (see [33], [32]). Definitions of trimmed means, Winsorized variances and the standard error of a trimmed mean can be found in [19] or [30, 31]. To test $H_0: \mu_{t1} - \mu_{t2} = 0 \equiv \mu_{t1} = \mu_{t2}$ (equality of population trimmed means), let $d_j = (n_j - 1)\hat{\sigma}_{wj}^2/h_j(h_j - 1)$, where $\hat{\sigma}_{wj}^2$ is the gamma-Winsorized variance and h_j is the effective sample size, that is, the size after trimming ($j = 1, 2$). Yuen's [33] test is

$$t_Y = \frac{\hat{\mu}_{t1} - \hat{\mu}_{t2}}{\sqrt{d_1 + d_2}}, \quad (4)$$

where $\hat{\mu}_{tj}$ is the γ -trimmed mean for the j th group and the estimated degrees of freedom are

$$v_Y = \frac{(d_1 + d_2)^2}{d_1^2/(h_1 - 1) + d_2^2/(h_2 - 1)}. \quad (5)$$

Bootstrapping

Following Westfall and Young [29] and as enumerated by Wilcox [30, 31], let $C_{ij} = Y_{ij} - \hat{\mu}_{tj}$; thus, the C_{ij} values are the empirical distribution of the j th group, centered so that the observed trimmed mean is zero. That is, the empirical distributions are shifted so that the null hypothesis of equal trimmed means is true in the sample. The strategy behind the bootstrap is to use the shifted empirical distributions to estimate an appropriate critical value. For each j , obtain a bootstrap sample by randomly sampling with replacement n_j observations from the C_{ij} values, yielding $Y_1^*, \dots, Y_{n_j}^*$. Let t_Y^* be the value of the test statistic based on the bootstrap sample. To control the FWE for a set of contrasts, the following approach can be used. Set $t_m^* = \max_j t_Y^*$, the maximum being taken over all $j \neq j'$. Repeat this process B times yielding

$t_{m1}^*, \dots, t_{mB}^*$. Let $t_{m(1)}^* \leq \dots \leq t_{m(B)}^*$ be the t_{mb}^* values written in ascending order, and let $q = (1 - \alpha)B$, rounded to the nearest integer. Then a test of a null hypothesis is obtained by comparing t_Y to $t_{m(q)}^*$ (i.e., whether $t_Y \geq t_{m(q)}^*$), where q is determined so that the FWE is approximately α . See [19, pp. 404–407], [29], or [32, 437–443].

Keselman, Wilcox, and Lix [16] present a SAS/IML [24] program which can be used to apply bootstrapping methods with robust estimators to obtain numerical results. The program can also be obtained from the first author's website at <http://www.umanitoba.ca/faculties/arts/psychology/>. This program is an extension of the program found in Lix and Keselman [18]. Tests of individual contrasts or families of contrasts may be performed (in addition omnibus main effects or interaction effects may be performed). The program can be applied in a variety of research designs. See [19].

Complex Comparisons

To introduce some methods that can be adopted when investigating complex comparisons among treatment group means we first provide some definitions. Specifically, we let

$$\psi = c_1\mu_1 + c_2\mu_2 + \dots + c_J\mu_J, \quad (6)$$

where the coefficients (c_j s) defining the contrast sum to one (i.e., $\sum_{j=1}^J c_j = 0$) represent the population contrast that we are interested in subjecting to a test of significance. To test $H_0: \psi = 0$, estimate ψ with

$$\hat{\psi} = c_1\bar{Y}_1 + c_2\bar{Y}_2 + \dots + c_J\bar{Y}_J. \quad (7)$$

The usual homoscedastic statistic is

$$t_{\hat{\psi}} = \frac{\hat{\psi}}{\sqrt{\text{MSE} \sum_{j=1}^J c_j^2/n_j}}. \quad (8)$$

A very popular simultaneous method for evaluating a set of m complex comparisons is to compare the P values associated with the $t_{\hat{\psi}}$ statistics to the Dunn–Bonferroni critical value α/m (see [17, p. 829] for the table of critical values).

One may also adopt stepwise MCPs when examining a set of m complex comparisons. These stepwise methods should result in greater sensitivity to

4 Multiple Comparison Tests

detect effects than the Dunn–Bonferroni [5] method. Many others have devised stepwise Bonferroni-type MCPs, for example, [10], [7], and so on. All of these procedures provide FWE control; the minor differences between them can result in small differences in power to detect effects. Thus, we recommend the Hochberg [7] sequentially acceptive step-up Bonferroni procedure because it is simple to understand and implement.

Hochberg’s [7] Sequentially Acceptive Step-up Bonferroni Procedure

In this procedure, the P values corresponding to the m statistics (e.g., $t_{\hat{\psi}_i}$) for testing the hypotheses $H_1, \dots, H_m$ are ordered from smallest to largest. Then, for any $i = m, m-1, \dots, 1$, if $p_i \leq \alpha/(m-i+1)$, the Hochberg procedure rejects all $H_{i'}$ ($i' \leq i$). According to this procedure, therefore, one begins by assessing the largest P value, p_m . If $p_m \leq \alpha$, all hypotheses are rejected. If $p_m > \alpha$, then H_m is accepted and one proceeds to compare $p_{(m-1)}$ to $\alpha/2$. If $p_{(m-1)} \leq \alpha/2$, then all H_i ($i = m-1, \dots, 1$) are rejected; if not, then $H_{(m-1)}$ is accepted and one proceeds to compare $p_{(m-2)}$ with $\alpha/3$, and so on.

The Dunn–Bonferroni [5] and Hochberg [7] procedures can be adopted to robust estimation and testing by adopting trimmed means and Winsorized variances, instead of the usual least squares estimators. That is, to circumvent the biasing effects of non-normality and variance heterogeneity researchers can adopt a heteroscedastic Welch-type statistic and its accompanying modified degrees of freedom, applying robust estimators. For example, the heteroscedastic test statistic for the Dunn–Bonferroni [5] and Hochberg [7] procedures would be

$$t_{\hat{\psi}} = \frac{\hat{\psi}}{\sqrt{\sum_{j=1}^J c_j^2 s_j^2 / n_j}}, \quad (9)$$

where the statistic is approximately distributed as a Student t variable with

$$df_W = \frac{\left(\sum_{j=1}^J c_j^2 s_j^2 / n_j \right)^2}{\sum_{j=1}^J [(c_j^2 s_j^2 / n_j)^2 / (n_j - 1)]}. \quad (10)$$

Accordingly, as we specified previously, one replaces the least squares means with trimmed means and least squares variances with variances based on Winsorized sums of squares. That is,

$$t_{\hat{\psi}_i} = \frac{\hat{\psi}_i}{\sqrt{\sum_{j=1}^J c_j^2 d_j}}, \quad (11)$$

where the sample comparison of trimmed means equals

$$\hat{\psi}_i = c_1 \bar{Y}_{i1} + c_2 \bar{Y}_{i2} + \dots + c_J \bar{Y}_{iJ} \quad (12)$$

and error degrees of freedom is given by

$$df_{W_i} = \frac{\left(\sum_{j=1}^J c_j^2 d_j \right)^2}{\sum_{j=1}^J [(c_j^2 d_j)^2 / (h_j - 1)]}. \quad (13)$$

A bootstrap version of Hochberg’s [7] sequentially acceptive step-up Bonferroni procedure can be obtained in the following manner. Corresponding to the ordered P values are the $|t_{\hat{\psi}_i}|$ statistics. These pairwise statistics can be rank ordered according to their size and thus p_m (the largest P value) will correspond to the smallest $|t_{\hat{\psi}_i}|$ statistic. Thus, the smallest $t_{\hat{\psi}_i}$ (or largest P value) is bootstrapped. That is, as Westfall and Young [29, p. 47] maintain ‘The resampled P values... are computed using the same calculations which produced the original P values... from the original... data.’ Accordingly, let $|t_{\hat{\psi}_{i(1)}}^*| \leq \dots \leq |t_{\hat{\psi}_{i(B)}}^*|$ be the $|t_{\hat{\psi}_{i(b)}}^*|$ values for this smallest comparison written in ascending order, and let $m_r = [(1 - \alpha)B]$. Then statistical significance is determined by comparing

$$|t_{\hat{\psi}_i}| \geq t_{\hat{\psi}_{i(m_r)}}^*. \quad (14)$$

If this statistic fails to reach significance, then the next smallest $|t_{\hat{\psi}_i}|$ statistic is bootstrapped and compared to the $m_r = [(1 - \alpha/2)B]$ quantile. If necessary, the procedure continues with the next smallest $|t_{\hat{\psi}_i}|$. Other approaches for FWE control with resampling techniques are enumerated by Lunneborg [19, pp. 404–407] and Westfall and Young [29].

It is important to note that, although we are unaware of any empirical investigations that have examined tests of complex contrasts with robust estimators, based on empirical investigations related to pairwise comparisons, we believe these methods would provide approximate FWE control under conditions of nonnormality and variance heterogeneity and should possess more power to detect group differences than procedures based on least squares estimators.

Numerical Example

We use an example data set presented in Keselman et al. [16] to illustrate the procedures enumerated in this paper. Keselman et al. modified a data set given by Karayanidis, Andrews, Ward, and Michie [13] where the authors compared the performance of three age groups (Young, Middle, Old) on auditory selective attention processes. The dependent reaction time (in milliseconds) scores are reported in Table 1.

We used the SAS/IML program demonstrated in [16, pp. 589–590] to obtain numerical results for tests of pairwise comparisons and a SAS/IML program that we wrote to obtain numerical results for tests of complex contrasts. Estimates of group trimmed means and standard errors are presented in Table 2.

Table 1 Example data set

Young	Middle	Old
518.29	335.59	558.95
548.42	353.54	538.56
524.10	493.08	586.39
666.63	469.01	530.23
488.84	338.43	629.22
676.40	499.10	691.84
482.43	404.27	557.24
531.18	494.31	528.50
504.62	487.30	565.43
609.53	485.85	536.03
584.68	886.41	594.69
609.09	437.50	645.69
495.15		558.61
502.69		519.01
484.36		538.83
519.10		
572.10		
524.12		
495.24		

Table 2 Descriptive Statistics [Trimmed Means and (Standard Errors)]

Young	Middle	Old
532.98 (15.27)	453.11 (26.86)	559.41 (11.00)

Three pairwise comparisons were computed: (1) Young versus Middle, (2) Young versus Old, and (3) Middle versus Old. The values of t_Y and v_Y for the three comparisons are (1) 6.68 and 11.55, (2) 1.97 and 19.72, and (3) 13.41 and 9.31; for .05 FWE control the critical value is 12.56. Accordingly, based on the methodology enumerated in this paper and the critical value obtained with the program discussed by Keselman et al. [16] only the third comparison is judged to be statistically significant.

We as well computed three complex comparisons: (1) Young versus the average of Middle and Old, (2) Middle versus the average of Young and Old, and (3) Old versus the average Young and Middle. Using the bootstrapped version of Hochberg's [7] step-up Bonferroni MCP, none of the contrasts are statistically significant. That is, the ordered $t_{\hat{\psi}_i}$ were 1.27 (comparison 2), 3.27 (comparison 1) and 3.50 (comparison 3). The corresponding critical $t_{\hat{\psi}_{r(m_r)}}^*$ were 2.20, 4.14, and 4.15, respectively.

Multiple Imputation

A method by which **missing values** in a data set are replaced by more than one, usually between 3 and 10, simulated versions. Each of the simulated complete datasets is then analyzed by the method relevant to the investigation at hand, and the results combined to produce estimates, standard errors, and confidence intervals that incorporate missing data uncertainty. Introducing appropriate random errors into the imputation process makes it possible to get approximately unbiased estimates of all parameters, although the data must be missing at random (*see **Dropouts in Longitudinal Data; Dropouts in Longitudinal Studies: Methods of Analysis***) for this to

be the case. The multiple imputations themselves are created by a Bayesian approach (*see **Bayesian Statistics** and **Markov Chain Monte Carlo and Bayesian Statistics***), which requires specification of a parametric model for the complete data and, if necessary, a model for the mechanism by which data become missing. A comprehensive account of multiple imputation and details of associated software are given in Schafer [1].

Multiple Informants

Most behavioral researchers agree that it is desirable to obtain information about subjects from multiple sources or informants. For example, the importance of using multiple informants for the assessment of behavior problems in children has long been emphasized in the phenotypic literature. Correlations between different informants' ratings of child behavior problems are typically low – in the range of 0.60 between informants with similar roles (e.g., parent–parent); 0.30 between informants who have different roles (e.g., parent–teacher); and 0.20 between self-reports and other informant ratings [1]. These low correlations are typically interpreted as indicating that different raters provide different information about behavior problems because they view the child in different contexts or situations; however, error and rater bias can also contribute to low agreement between informants. Whatever the reasons for disagreement among informants, the use of multiple informants allows researchers to gain a fuller understanding of the behavior under study.

In quantitative genetic analyses, relying on a single informant may not paint a complete picture of the etiology of the behavior of interest. Using the above example, parent and teacher ratings assess behaviors in very different contexts; consequently, the genetic and environmental factors that influence behaviors at home might differ from those that influence the same behaviors in the classroom. There may also be some question as to whether parents and teachers actually are assessing the *same* behaviors. In addition, informants' response tendencies, standards, or behavioral expectations may affect their ratings – **rater biases** that cannot be detected without information from multiple informants. Analysis of data from multiple informants can inform about the extent to which different informants' behavioral ratings are influenced by the same genetic and environmental factors, and can explain why there is agreement and/or disagreement amongst informants.

Three classes of quantitative genetic models have been applied to data from multiple informants: biometric models, psychometric models, and bias models [5]. Each makes explicit assumptions about the reasons for agreement and disagreement among informants. Biometric models such as the **Independent Pathway** model [3] posit that genes and environments

contribute to **covariance** between informants through separate genetic and environmental pathways. This model decomposes the genetic, **shared environmental**, and **nonshared environmental** variances of multiple informants' ratings (e.g., parent, teacher, and child) into genetic and environmental effects that are common to all informants, and genetic and environmental effects that are specific to each informant. Under this model, covariance between informants can arise due to different factors. That is, although all informants' ratings may be intercorrelated, the correlation between any two informants' ratings may be due to different factors (e.g., the correlation between parent and teacher could have different sources than the correlation between parent and child). Like the **Cholesky Decomposition** (also a biometric model), the Independent Pathway Model can be considered to be 'agnostic' in that it does not specify that the different informants are assessing the same phenotype, rather, it just allows that the phenotypes being assessed by each informant are correlated [2].

The Psychometric or **Common Pathway model** [3, 4] is more restrictive, positing that genes and environments influence covariation between raters through a *single* common pathway. This model suggests that correlations between informants arise because they are assessing a common phenotype. This common phenotype is then influenced by genetic and/or environmental influences. As is the case for the Independent Pathway model, this model also allows genetic and environmental effects specific to each informant. Under this model, genetic and/or environmental sources of covariance are the same across all informants. Informants' ratings agree because they tap the same latent phenotype (i.e., they are assessing the same behaviors). Informants' ratings differ because, to some extent, they also assess different phenotypes due to the fact that each informant contributes different but valid information about the target's behavior.

As with the Psychometric model, the **Rater Bias model** [2, 6] assumes that informants agree because they are assessing the same latent phenotype that is influenced by genetic and environmental factors; however, this model also assumes that disagreement between informants is due to rater bias and unreliability. That is, this model does not include informant-specific genetic or environmental influences – anything that is not reliable trait variance (i.e., the common phenotype) is bias or error, both of which are estimated in the model. Rater biases refer to the

2 Multiple Informants

informant's tendency to consistently overestimate or underestimate the behavior of targets [2]. Because bias is conceptualized as consistency *within* an informant *across* targets, the Rater Bias model requires that the same informant assess both members of a twin or sibling pair. Other multiple informant models do not require this.

All of the above models allow the estimation of **genetic and environmental correlations** (i.e., degree of genetic and/or environmental overlap) between informants, and the extent to which genetic and environmental factors contribute to the phenotypic correlations between informants (i.e., bivariate heritability and environmentality). Comparisons of the relative fits of the different models make it possible to get some understanding of differential informant effects. By comparing the Biometric and Psychometric models, it is possible to determine whether it is reasonable to assume that different informants are assessing the same phenotypes. That is, if a Biometric model provides the best fit to the data, then the possibility that informants are assessing different, albeit correlated, phenotypes must be considered. Similarly, comparisons between the Psychometric and Rater Bias models inform about the presence of valid informant differences versus rater biases.

Multiple Linear Regression

Multiple regression addresses questions about the relationship between a set of independent variables (*IVs*) and a dependent variable (*DV*). It can be used to describe the relationship, to predict future scores on the *DV*, or to test specific hypotheses based on scientific theory or prior research. Multiple regression most often focuses on linear relationships between the *IVs* and the *DV*, but can be extended to examine other forms of relationships.

Multiple regression begins by writing an equation in which the *DV* is a weighted linear combination of the independent variables. In general, the regression equation may be written as $Y = b_0 + b_1X_1 + b_2X_2 + \dots + b_pX_p + e$. Y is the *DV*, each of the X s is an independent variable, each of the b s is the corresponding regression coefficient (weight), and e is the error in prediction (residual) for each case. The linear combination excluding the residual, $b_0 + b_1X_1 + b_2X_2 + \dots + b_pX_p$, is also known as the predicted value or $\hat{Y}$, the score we would expect on the *DV* based on the scores on the set of *IVs*.

To illustrate, we use data from 56 live births taken from [4]. The *IVs* were the *Age* of the mother in years, the *Term* of the pregnancy in weeks, and the *Sex* of the infant (0 = girls, 1 = boys). The *DV* is

the *Weight* of the infant in grams. Figure 1(a) is a **scatterplot** of the *Term*, *Weight* pair for each case. Our initial analysis (Model 1) predicts infant *Weight* from one *IV*, *Term*. The regression equation is written as $Weight = b_0 + b_1Term + e$. The results are shown in Table 1. $b_0 = -2490$ is the intercept, the predicted value of *Weight* when *Term* = 0. $b_1 = 149$ is the slope, the number of grams of increase in *Weight* for each 1-week increase in *Term*. Each of the regression coefficients is tested against a population value of 0 using the formula, $t = b_i/s_{b_i}$, with $df = n - p - 1$, where s_{b_i} is the estimate of the standard error of b_i . Here, $n = 56$ is the sample size and $p = 1$ is the number of predictor variables. We cannot reject the null hypothesis that the infant's *Weight* at 0 weeks (the moment of conception) is 0 g, although a term of 0 weeks for a live birth is impossible. Hence, this conclusion should be treated very cautiously. The test of b_1 indicates that there is a positive weight gain for each 1-week increase in *Term*; the best estimate is 149 g per week. The 95% confidence interval for the corresponding population regression coefficient b_1 is $b_1 \pm t_{0.975} s_{b_1} = 149 \pm (2)(38.8) = 71.4$ to 226.6. $R^2 = 0.21$ is the squared correlation between Y and $\hat{Y}$ or, alternatively, $.21$ is $SS_{\text{predicted}}/SS_{\text{total}}$, the proportion of variation in *Weight* accounted for by *Term*.

Model 2 predicts *Weight* from *Term* and mother's *Age*. Figure 1(b) portrays the relationship between *Weight* and *Age*. To improve the interpretability of the intercept [9], we mean center *Term*, $Term_c = Term -$

Figure 1 Scatterplots of raw data (a) Weight vs. Term (b) Weight vs. Age *Note:* x represents male; o represents female. Each point represents one observation. The best fitting straight line is superimposed in each scatterplot.

Total	55	16753984			

$\text{Mean}(\text{Term})$, and Age , $\text{Age}_C = \text{Age} - \text{Mean}(\text{Age})$. In this sample, $\text{Mean}(\text{Term}) = 39.6$ weeks and $\text{Mean}(\text{Age}) = 26.3$ years. The results are presented in Table 2. The intercept b_0 now represents the predicted value of $\text{Weight} = 3413$ g when Term_C and Age_C both equal 0, at the mean Age of all mothers and mean Term length of all pregnancies in the sample. This value is equal to the mean birth weight in the sample. $b_1 = 141$ is the slope for Term , the gain in Weight for each 1-week increase in Term , holding the mother's Age constant. $b_2 = 48$ is the slope for Age , the gain in Weight for each 1-year increase in mother's Age , holding Term constant. Mean centering does not affect the value of the highest order regression

coefficients, here the slopes. The addition of Term to the equation results in an increase in R^2 from 0.21 to 0.38.

Model 3 illustrates the addition of a categorical IV , infant Sex , to the regression equation. For G categories, $G - 1$ code variables are needed to represent the categorical variable. Sex has two categories (female, male), so one code variable is needed. Several different schemes including dummy, effect, and contrast codes are available; the challenge is to select the scheme that provides the optimal interpretation for the research question [3]. Here we use a dummy code scheme in which 0 = female and 1 = male (see **Dummy Variables**). Table 3 presents

Table 3 Model 3: regression of infant weight on term, mother's age, and sex

Diagnostic Statistics	Largest Absolute Value
Leverage (h_{ii})	0.24
Distance (t_i)	2.49
Global Influence (DFFITS _{<i>i</i>})	0.66
Specific Influence	
DFBETAS _{<i>ij</i>} – Term	–0.46
DFBETAS _{<i>ij</i>} – Age	0.56
DFBETAS _{<i>ij</i>} – Sex	0.36

the results. Again, $Term_C$ and Age_C are mean centered.

The intercept b_0 now represents the predicted value of *Weight* when Age_C and $Term_C$ are 0 (their respective mean values) and $Sex = 0$ (female infant). $b_1 = 141$ represents the slope for $Term_C$, $b_2 = 48$ represents the slope for Age_C , and $b_3 = -18$ indicates that males are on average 18 g lighter holding Age and $Term$ constant. The t Tests indicate that the intercept, the slope for $Term$ and the slope for Age are greater than 0. However, we cannot reject the null hypothesis that the two sexes will have equal birth weights in the population, holding Age and $Term$ constant. The 95% confidence intervals indicate the plausible range for each of the regression coefficients in the population. Finally, the R^2 is still 0.38. The gain in prediction can be tested when any set of 1 or more predictors is added to the equation,

$$F = \frac{(SS_{\text{regression—full}} - SS_{\text{regression—reduced}})/df_{\text{set}}}{SS_{\text{residual—full}}/df_{\text{residual—full}}} \quad (1)$$

Comparing Model (3), the full model with all 3 predictors, with Model (1), the reduced model that only included $Term$ as a predictor, we find

$$F = \frac{(6322743 - 3598397)/2}{10431241/52} = 22.5;$$

$$df = 2, 54; \quad p < 0.001 \quad (2)$$

The necessary Sums of Squares (SS) are given in Tables 1 and 3 and the df_1 is the difference in the number of predictors between the full and reduced models, here $3 - 1 = 2$, and the df_2 is identical to that of the full model. This test indicates that adding Age and Sex to the model leads to a statistically significant increase in prediction.

Table 3 also presents the information about the relationship between each *IV* and the *DV* in three other metrics. The **standardized regression coefficient** indicates the number of standard deviations (*SD*) the *DV* changes for each 1 *SD* change in the *IV*, controlling for the other *IVs*. The squared semipartial (part) correlation indicates the unique proportion of the total variation in the *DV* accounted for by each

4 Multiple Linear Regression

IV. The squared partial correlation (*see Partial Correlation Coefficients*) indicates the unique proportion of the remaining variation in the DV accounted for by an IV after the contributions of each of the other IVS have been subtracted out. The squared partial correlation will be larger than the squared semipartial correlation unless the other IVS collectively do not account for any variation.

More complex forms of multiple regression models can also be specified. A quadratic relationship [1] can be expressed as $Y = b_0 + b_1X + b_2X^2 + e$. An interaction [1] in which Y depends on the combination of X_1 and X_2 can be expressed as $Y = b_0 + b_1X + b_2X_2 + b_3X_1X_2 + e$. In some cases such as when there is a very large range on the DV, Y may be transformed by replacing it by a function of Y , for example, $\log(Y)$. Similar transformations may also be performed on each IV [4]. Nonlinear models which follow a variety of mathematical functions can also be estimated [6, 8] (*see Nonlinear Models*). For example, the growth of learning over repeated trials often initially increases rapidly and then gets slower and slower until it approaches a maximum possible value (asymptote). This form can often be represented by an exponential function.

Multiple regression is adversely affected by violations of assumptions [3, 4, 6]. First, data may be clustered because individuals are measured in groups or repeated measurements are taken on the same individuals over time (nonindependence) (*see Linear*

Multilevel Models and Generalized Linear Mixed Models). Second, the variance of the residuals around the regression line may not be constant (heteroscedasticity). Third, the residuals may not have a normal distribution (nonnormality). Violations of these assumptions may require special procedures such as random coefficient models (3) for clustering and the use of alternative estimation procedures for non-constant variance to produce proper results, notably correct standard errors. Careful examination of plots of the residuals (see Figure 2) can diagnose problems in the regression model and lead to improvements in the model (e.g., addition of an omitted IV).

Another problem is **outliers**, extreme data points that are far from the mass of observations [3, 4, 6]. Outliers may represent observational errors or extremely unusual true cases (e.g., an 80-year old college student). Outliers can potentially profoundly affect the values of the regression coefficients, even reversing the sign in extreme cases. Outlier statistics are case statistics, with a set of different diagnostic statistics being computed for each case i in the data set. Leverage (h_{ii}) measures how extreme a case is in the set of IVS; it is a measure of the distance of case i from the centroid of the X s (the mean of the IVS). Distance measures the discrepancy between the observed Y and the predicted $\hat{Y}$ ($Y - \hat{Y}$) for each case, indicating how poorly the model fits the case in question. Because outliers can affect the slope of the

Figure 2 Model checking plots (a) Residuals vs. Predicted Values (b) Q-Q Plot of Residuals vs Normal Distribution
Note: In (a), residuals should be approximately evenly distributed around the 0-line if the residuals are homoscedastic. In (b), the residuals should approximately fit the superimposed straight line if they are normally distributed. The assumptions of homoscedasticity and normality of residuals appear to be met.

regression line, the externally Studentized residual t_i is used rather than the simple residual e as t_i provides a much clearer diagnosis. Conceptually, the regression equation is estimated with case i deleted from the data set. The values of the IVS for case i are substituted into this equation to calculate $\hat{Y}_{i(i)}$ for case i . t_i is the standardized difference between the observed value of Y_i and $\hat{Y}_{i(i)}$. Influence, which is the combination of high leverage and high distance, indicates the extent to which the results of the regression equation are affected by the outlier. $DFFITS_i$ is a standardized measure of global influence which describes the number of SD s by which $\hat{Y}$ would change if case i were deleted. $DFFITS_i = t_i \sqrt{(h_{ii}/1 - h_{ii})}$. (Cook's D_i is a closely related alternative measure of global influence in a different metric). Finally, $DFBETAS_{ij}$ is a standardized measure of influence which describes the number of SD s regression coefficient b_j would change if case i were deleted. Cases with extreme values on the outlier diagnostic statistics should be examined with suggested rule of thumb cutoff values for large sample sizes being $(2(p+1)/n)$ for h_{ii} , ± 3 or ± 4 for t_i , $\pm 2\sqrt{(p+1)/n}$ for $DFFITS_i$, and $\pm (2/\sqrt{n})$ for $DFBETAS_{ij}$. No extreme outliers were identified in our birth weight data set. Methods of addressing outliers include dropping them from the data set and limiting the conclusions that are reached and using robust regression procedures that down weight their influence (see **Influential Observations**).

In summary, multiple regression is a highly flexible method studying the relationship between a set of IVS and a DV. Different types of IVS may be studied and a variety of forms of the relationship between each IV and the DV may be represented. Multiple regression requires attention to its assumptions and to possible outliers to obtain optimal results and improve the model. A chapter length introduction [2], full length introductions

for behavioral scientists [3, 5, 7], and full length introductions for statisticians [6, 8, 10] to multiple regression are available. Numerous multiple regression programs exist, with SPSS Regression and SAS PROC Reg being most commonly used (see **Software for Statistical Analyses**). Cook and Weisberg [1] offer an excellent freeware program ARC <http://www.stat.umn.edu/arc/>.

Multiple Testing

The multiple-testing problem arises when a person or team performs two or more significance tests, because the probability of finding at least one significant result exceeds the nominal probability α . Multiple-testing methods are designed to correct for this liberal bias. Typical cases of multiple tests are the multiple comparisons of cell means in **analysis of variance**, testing all the values in a matrix of correlations (see **Correlation and Covariance Matrices**), testing all the slopes in a **multiple linear regression**, testing each cell in a **contingency table** for the cell frequency's deviation from its expected value, and finding multiple tests of the same general question in a review of scientific literature. The multiple-comparisons problem has received far more attention than the others, and a separate article is devoted to that topic (see **A Priori v Post Hoc Testing**). We also cover that multiple-comparisons problem briefly here, but we focus more heavily on the more general problem.

If p_m denotes the most significant value among B significance levels, the problem is to find the probability that a value at least as small as p_m would have been found just by chance in the total set of B values. We shall denote this probability as PC , for 'corrected p_m '. We do not generally assume that the B trials are statistically independent; of the five examples in the opening paragraph, trials are independent only in the last one, in which the various significance levels are obtained from completely different experiments. When independence does exist, the exact formula for PC is well known: $(1 - p_m)$ is the probability of failing to find the p_m in question on any one trial, so $(1 - p_m)^B$ is the probability of failing on all B trials, so $1 - (1 - p_m)^B$ is the probability of finding at least that level on at least one trial. Thus $PC = 1 - (1 - p_m)^B$.

Here we review the most widely used methods for correcting for multiple tests and also consider more general questions that arise when dealing with multiple tests. We begin with a review of methods.

The Bonferroni Method

Ryan [5] and Dunn [3] were actually the first prominent advocates of the method that is now generally called the *Bonferroni* method, but nevertheless

here we shall call the method by its most widely used name. The Bonferroni method is noteworthy for its extreme flexibility; it can be applied in all of the cases mentioned in our opening paragraph, plus many more. It is also remarkably simple. If you have selected the most significant value p_m out of B significance levels that you computed, then you simply multiply these two values together, so $PC = B \times p_m$. The Bonferroni method has become increasingly practical in recent years because modern computer packages can usually give the exact values of very small p values; these are, of course, necessary for the Bonferroni method.

There is no requirement that the tests analyzed by the Bonferroni method be statistically similar. For instance, they may be any mixture of parametric and nonparametric tests. In theory, they could even be a mixture of one-tailed and two-tailed tests, but scientifically, the conclusions would usually be most meaningful if all tests were one or the other.

If tests are independent and the true PC is .05 or below, the Bonferroni method has only a slight conservative bias in comparison to the exact formula mentioned above. By trying the exact formula and the Bonferroni formula with various values of B , one can readily verify that when $B < 10^9$ and the exact formula yields $PC = .05$, the Bonferroni formula never yields PC over .0513. But when the exact PC is very high, the Bonferroni PC may be far higher still – even over 1.0. Thus, if the Bonferroni formula yields $PC > .05$ for independent tests, you should take the extra time to calculate the exact value.

Contrary to intuition, the Bonferroni method can be reasonably powerful even when B is very large. For instance, consider a Pearson correlation of .5 in a sample of 52 cases. We have $p < .000001$, which would yield PC below .05 even if B were 50 000.

Ryan [6] has shown that the Bonferroni method is never too liberal, even if the various tests in the analysis are nonindependent. The more positively correlated the tests in the analysis are, the more conservative the Bonferroni test is relative to some theoretically optimum test. One can think of the ordinary two-tailed test as a one-tailed test corrected by a Bonferroni factor of 2 to allow for the possibility that the investigator chose the direction *post hoc* to fit the data. There is no conservative bias in the two-tailed test because the two possible one-tailed tests are perfectly negatively correlated – they can never

2 Multiple Testing

both yield positive results. But there is no liberal bias even in this worst case.

The Bonferroni method easily handles a problem that arises in the area of multiple comparisons, which the classical methods for multiple comparisons cannot handle. If you have decided in advance that you are interested in only some subset of all the possible comparisons, and you test only those, then you can apply the Bonferroni method to correct for the exact number of tests you have performed.

There is also Bonferroni layering. If the most significant of k results is significant after a Bonferroni correction, then you can test the next most significant result using a Bonferroni factor of $(k - 1)$ because that is the most significant of the remaining $(k - 1)$ results. You can then continue, testing the third, fourth, and other most significant results using correction factors of $(k - 2)$, $(k - 3)$, and so on.

Multiple Comparisons

The opening paragraph gave five instances of the multiple-tests problem, and there are many others. Thus, the problem of multiple comparisons in analysis of variance is just one of many instances. But this one instance has attracted extraordinary attention from statisticians. Lengthy reviews of this work appear in works like [4] and [7], and the topic is covered in a separate article in this encyclopedia (*see A Priori v Post Hoc Testing*). Thus, we mention only a few highlights here.

In analysis of variance, a pairwise comparison is a test of the difference between two particular cell means. For simplicity, we shall emphasize one-way analyses of variance, though our discussion applies with little change to more complex designs. If there are k cells in a design, then the number of possible pairwise comparisons is $k(k - 1)/2$. Thus, one valid approach is to compute all possible pairwise values of t , test the most significant one using a Bonferroni correction factor of $k(k - 1)/2$, and then use Bonferroni layering to test the successively smaller values of t . This approach is very flexible: it does not require equal cell frequencies or the assumption of equal within-cell variances, and tests may be one-tailed, two-tailed, or even mixed. Virtually all alternative methods are less flexible but do gain a small amount of power relative to the method just mentioned.

Several of these methods use the *studentized range*, defined as $sr = (M_i - M_j)/\sqrt{(MSE/n_h)}$, where M_i and M_j are the two cell means in question, MSE is the mean squared error, and n_h is the **harmonic mean** of the two cell frequencies. This is essentially the t that one would calculate to test the difference between just those two cell means, with two differences: sr uses the pooled variance for the entire analysis rather than for just the two cells being tested and sr is multiplied by an extra factor of $\sqrt{2}$. The latter difference arises because $n_h = 2/(1/n_i + 1/n_j)$, which is twice the comparable value used in the ordinary t Test. The studentized range is then compared to critical values specific to the method in question.

Perhaps the best-known method using sr is the Tukey HSD (honestly significant difference) method. This provides critical values for the largest of all the $k(k - 1)/2$ values of sr for a given data set. The HSD test is slightly more powerful than the Bonferroni method. For instance, when $k = 10$, residual degrees of freedom = 60, and $\alpha = .05$ two-tailed, the critical t -values for the Tukey and Bonferroni methods are 3.29 and 3.43 respectively.

The Duncan method was designed to address this same problem; it also provides tables of critical values of sr . This method is widely available but is commonly considered logically flawed. It has the unusual property that the larger the k , the more likely the outcome is to be significant when the null is true. For instance, if $k = 100$ and if tests are at the .05 level and if all 100 true cell means are equal, the probability is nevertheless .9938 that at least one comparison will be found to be significant. The general expression for such values is $1 - (1 - \alpha)^{k-1}$. Duncan argued that this is reasonable, since when k is large, the largest cell difference is very likely to reflect a real difference. This view seems overly optimistic – if you were testing 100 different pills, each promising to make users lose 20 pounds of weight in the next month, would you want to use a statistical method almost guaranteed to conclude that at least one was effective?

The Fisher protected t Test is also called the LSD (least significant difference) or protected LSD test. Unlike the HSD or Duncan method, it requires no special tables. Rather the investigator first tests the overall F , and if it is significant, tests as many comparisons as desired with ordinary t Tests.

This test is controversial, and its advantages and disadvantages are discussed further below.

The Dunnett method is for a different problem in which the k cells include $k - 1$ treatment groups and one control group, and the only comparisons to be tested are between the control group and the treatment groups. It uses a studentized range. The Bonferroni method could be used here with a correction factor of $k - 1$. The Dunnett method is slightly more powerful than the Bonferroni method.

The Scheffé method is the only method discussed here that applies to comparisons involving more than two cell means, such as when you average the highest 3 of 10 cell means, average the lowest 3 cell means, and want to test the difference between the two averages. Weighted averages may also be used. Since the number of possible weighted averages is infinite, the Bonferroni method cannot be used because B would be infinite. The Scheffé method allows the investigator to use any *post hoc* strategy whatsoever to select the most significant comparisons and to test as many comparisons as desired. When corrected by the Scheffé formula, the tests will still be valid. The Scheffé formula is simple: compute t for the comparison of interest, then compute $F = t^2/(k - 1)$, and compare F to an F table using the same df one would use to test the overall F for that data set. The Scheffé method is less powerful than any of the other methods discussed here and is thus not recommended if any of the other methods are applicable.

Layering Methods for Multiple Comparisons

Suppose there are 10 cells in a one-way analysis of variance, and you number the cells in the order of their means, from 1 (lowest) to 10 (highest). Suppose that by the HSD method you have found a significant difference between cell means 1 and 10. You might then want to test the difference between means 1 and 9 and the difference between means 2 and 10. If the 1 to 9 difference is significant, you might want to test the difference between means 1 and 8 and the difference between means 2 and 9. Continuing in this way so long as results continue to be significant, you might ultimately want to test the difference between adjacent cell means. This entire process is called *layering* or *step-down analysis*, and several methods for it have been proposed.

The Newman–Keuls method simply uses the HSD tables for lower values of k , setting $k = m + 1$ where m is the difference between the ranks of the two means being compared. For instance, suppose you are testing the difference between means 2 and 7, so $m = 5$. These means are the highest and lowest of a set of 6 means, so use the HSD tables with $k = 6$. This method has been criticized as too liberal, but is defended in a later section.

The Ryan–Einot–Gabriel–Welsch method is a noncontroversial Bonferroni-type method for the layering problem in multiple comparisons. Compute the t and p for any comparison in the ordinary way, but then multiply p by a Bonferroni correction factor of $k \times m/2$.

Contingency Tables

Suppose you want to test each cell in a contingency table for a difference between that cell's observed and expected frequency. The sufficient statistics for that null hypothesis are the cell frequency, the corresponding column and row totals, and the grand total for the entire table. Thus you can use those four frequencies to construct a 2×2 table in which the four frequencies are the frequency in the focal cell, all other cases in the focal row, all other cases in the focal column, and all cases not in any of the first three. One can then apply any valid 2×2 test to that table. If you do this for each cell in the table, the Bonferroni method can be used to correct for multiple tests. If R and C are the numbers of rows and columns, then the total number of tests is $R \times C$, so that should be the Bonferroni correction. Bonferroni layering may be used.

It could be argued that once a cell has been identified as an outlying cell, its frequency should somehow be ignored in computing the expected frequencies for other cells. As explained in [1], that problem can be addressed by fitting models with 'structural zeros' for cells already identified as outliers.

What Tests Should One Correct for?

Particularly in the multiple-comparisons area, writers have generally assumed that the set of tests used in a single correction should be all the tests in a single 'experiment', or in a complex experiment, all

4 Multiple Testing

the tests in a single ‘effect’ – that is, all the tests in a single line of the analysis of variance table. The corrected significance levels calculated in this way are called ‘experimentwise’ levels in the former case or ‘familywise’ levels in the latter. But these answers do not apply to many of the examples in our opening paragraph, such as when one is reviewing many studies by different investigators. The broader answer would seem to be that one is trying to reach a particular conclusion, and one should correct for all the tests one scanned to try to support that conclusion. It should be plausible, to at least some people, that all the individual null hypotheses in the scanned set are true, so that any results that are significant individually appeared mainly because so many tests were scanned. Thus, for instance, we would never have to correct for all the tests ever performed in the history of science because there is no serious claim that all the null hypotheses in the history of science are true – the dozens of reliable appliances we use every day contradict that hypothesis.

A single result can drastically change the set that seems appropriate to correct for. For instance, suppose you search the literature on a topic and find 50 significance tests by various investigators. They do not all test the same null hypothesis, though all are in the same general area. One possibility is that all 50 null hypotheses are true, and that might be plausible. But suppose you can divide the 50 tests into 5 groups (A to E) on the basis of their scientific content. Suppose you find that single tests in groups B and D are significant even after any reasonable correction. Then you can dismiss the null hypotheses that there are no real effects in areas B and D, and you might evaluate other tests in those areas with no further correction for multiple tests. Of course, you have also dismissed the null hypothesis of no real effects in the total set of 50. Thus, in areas A, C, and E, you might apply corrections for multiple tests, correcting each only for the number of tests in those subareas. Thus, one or two highly significant results may, as in this example, greatly change your view of what ‘sets’ need to be tested. The choice of the proper sets should be made by subject-matter experts, not by statistical consultants.

This line of reasoning can be used to defend the Newman–Keuls method. In a one-way analysis of variance, suppose the set of k cell means is divided into subsets such that all true cell means within a subset are equal but all the subsets differ from each

other. In that situation, the Newman–Keuls method fails the familywise and experimentwise criteria of validity because the significant results found in the early stages of the layering process will lead the analyst to perform multiple tests in the final stages, and it is highly probable that some of those later tests will be significant (producing Type 1 errors) just by chance. But it can be argued that if all the cell means in one subset have been shown to differ from all those in another subset, then tests within the two subsets are now effectively in two different scientific areas, even though all the cell means were originally estimated in the same ‘experiment’. We all agree that tests in different scientific areas need not be corrected for each other, even though that policy does mean that on any given day some type 1 errors will be made somewhere in the world. By that line of reasoning, the Newman–Keuls method seems valid.

It is harder to see any similar justification for the Fisher LSD method. If one of 10 cell means is far above the other 9, the overall F may well be significant. But this provides no obvious reason for logically separating the lower 9 cell means from each other. If you have selected the largest difference among these 9 cell means, you would be selecting the largest of 36 comparisons. Yet, LSD would allow you to test that with no correction for *post hoc* selection. There is no clear justification for such a process. The Duncan method is far more liberal than LSD and also seems unreasonable.

An Apparent Contradiction

Investigators often observe significant results in an overall test of the null hypothesis – for instance, a significant overall F in a one-way analysis of variance – but then they find no significant individual results. This can happen even without corrections for multiple tests but is far more common when corrections are made. What conclusions can be drawn in such cases?

To answer this question, it is useful to distinguish between specific and vague conclusions. A vague conclusion includes the phrase ‘at least one’ or some similar phrase. For instance, in the significant overall F just mentioned, the proper conclusion is that ‘at least one’ of the differences between cell means must be nonzero. But no specific conclusions can be

drawn – conclusions specifying exactly which differences are nonzero, or even naming one difference known to be nonzero.

Results like this occur simply because it takes more evidence to reach specific conclusions than vague conclusions. This fact is not limited to statistics. For instance, a detective may conclude after only a few hours of investigation that a murder must have been committed by ‘at least one’ of five people but may take months to name one particular suspect, or may never be able to name one. Thus the situation we are discussing arises because the sample contains enough evidence to reach a vague conclusion but not enough evidence to reach a specific conclusion.

For another example, suppose five coins are each flipped 10 times to test the hypothesis that all are fair coins, against the one-tailed hypothesis that some or all are biased toward heads. Suppose the numbers of heads for the five coins are, respectively, 5, 6, 7, 8, and 9. Even the last of the 5 coins is not significantly different from the null at the .05 level after correction for *post hoc* selection; using the exact correction formula for independent tests yields $PC = .0526$ for that coin. But collectively, there are 35 heads in 50 flips, and that result is significant with $p = .0033$. We can reach the vague conclusion that at least one of the coins must be biased toward heads, but we cannot reach any specific conclusions about which one or ones.

More Techniques for Independent Tests, and the ‘File-Drawer’ Problem

Examples like the last one raise an interesting question: If an overall test is significant but no tests for specific conclusions can be reached, can we reach a conclusion that is more specific than the one already reached, even if not as specific as we might like? The answer is yes. For instance, in the five-coin example, consider the conclusion that at least one of the last two coins is biased toward heads. If we ignored the problem of *post hoc* selection we would notice that those two coins showed 17 heads in 20 trials, yielding $p = .0013$ one-tailed. But there are 10 ways to select two coins from five, so we must make a 10-fold Bonferroni correction, yielding $PC = .013$.

We thus have a significant result yielding a conclusion more specific than the conclusion that at least one of the five coins is biased toward heads. This kind of technique seems particularly useful in literature reviews, sometimes allowing conclusions that are positive and fairly specific even when no individual studies are significant after correction for *post hoc* selection. Methods for this problem are discussed at length in [2].

These methods also permit allowance for the file-drawer problem – the problem of possible unpublished negative results. In our example, suppose we were worried that as many as four other coins had been flipped but their results had not been given to us because they came out negative. Thus, our two coins with 17 heads between them in fact yielded the best results of nine coins, not merely the best of five. Thus our appropriate Bonferroni correction is $9!/(2! 7!) = 36$. Applying this correction we have $PC = 36 \times .0013 = .0464$. Thus our two-coin conclusion is significant beyond the .05 level even after allowing for the possibility that we are unaware of several negative results.

Multitrait–Multimethod Analyses

The multitrait-multimethod (MTMM) design provides a framework for assessing the validity of psychological measures [5] (*see Measurement: Overview*). Although a variety of MTMM research designs exist, all share a critical feature: the factorial crossing of constructs and measurement procedures (i.e., a set of constructs is assessed with each of several different methods of measurement). MTMM designs have been used to confirm that measures intended to reflect different constructs do assess distinct constructs (i.e., discriminant validity), to confirm that measures intended to assess a given construct are in fact assessing the same construct (i.e., convergent validity), and to gauge the relative influence of method and trait effects.

Traditional Approach to MTMM Analyses

Although MTMM studies are ubiquitous, there has been surprisingly little consensus on how MTMM data should be analyzed. Traditionally, data have been analyzed by visually examining four properties of the resulting correlation matrix of measures in MTMM designs [5]. The first property is ‘monotrait-heteromethod’ correlations (i.e., correlations between different measures of the same construct). Large monotrait-heteromethod correlations indicate convergent validity. These correlations cannot be interpreted in isolation, however, because distinct measures of a construct may covary for other reasons (e.g., because measures tap unintended constructs or contain systematic measurement error). Thus, the ‘heterotrait-heteromethod’ correlations (i.e., correlations between different measures of different constructs) should also be examined. Each monotrait-heteromethod correlation should be larger than the heterotrait-heteromethod correlations that share the same row or column in the matrix. In other words, correlations between different measures of the same construct should be larger than correlations between construct/measure combinations that share neither construct nor measurement procedure. Third, the ‘heterotrait-monomethod’ correlations (i.e., correlations between measures of different

constructs with the same measurement procedures) should be inspected. Monotrait-heteromethod correlations should be larger than heterotrait-monomethod correlations. That is, observations of the same construct with different measurement procedures should be more strongly correlated than are observations of different constructs using the same measurement procedures. Finally, all of the heterotrait triangles should be examined. These triangles are the correlations between each of the constructs measured via the same procedures and the correlations between each of the constructs measured via different procedures. Similar patterns of associations among the constructs should be evident in each of the triangles.

Although the traditional analytical approach has proven useful, it has significant limitations. For example, it articulates no clear assumptions regarding the underlying nature of traits and methods (e.g., whether traits are correlated with methods) and it implies some assumptions that are unrealistic (e.g., random measurement error is ignored). Further, it provides no means for formally assessing the plausibility of underlying assumptions, and it is also cumbersome to implement with large matrices. Finally, implementation of the traditional approach is an inherently subjective and imprecise process. Some aspects of the matrix may be consistent with the guidelines, whereas others may not, and there are gradations to how well the requirements have been met. Because of these limitations, formal statistical procedures for analyzing MTMM data have been developed. The goal of these approaches is to allow for more precise hypothesis testing and more efficient summarizing of patterns of associations within MTMM correlation matrices.

Analysis of Variance (ANOVA) Approach

The **analysis of variance (ANOVA)** approach [6, 9, 14] is rooted in the notion that every MTMM observation is a joint function of three factors: trait, method, and person. ANOVA procedures can be used to parse the variance in MTMM data into that which is attributable to each of these factors and to their interactions. Variance attributable to person (i.e., a large person main effect) is often interpreted as evidence of convergent validity, but not as defined in the classic Campbell and Fiske [5] sense. Rather, it indicates that a general factor accounts for a

substantial portion of the variance in the MTMM matrix (which is useful as a comparison point for higher-order interactions). Variance attributable to the person by trait interaction reflects the degree to which people vary in their level of each trait, averaging across methods of measurement. A large person by trait interaction implies low heterotrait correlations (i.e., discriminant validity). Discriminant validity is high when the person by trait interaction accounts for substantially more variance than the person main effect. Variance attributable to the person by method interaction reflects the degree to which people vary in their responses to the measurement procedures, averaging across traits. Large person by method interactions are undesirable because they indicate that methods of measurement account for substantial variance in the MTMM matrix.

The ANOVA approach is useful in that it parsimoniously summarizes the pattern of correlations in an MTMM matrix, and in that it assesses the relative contribution of various sources of variance. However, the ANOVA also requires unrealistic assumptions (i.e., uncorrelated trait factors, uncorrelated method factors, equivalent reliability for measures, the person by trait by method interaction contains only error variance). Furthermore, the use of the person main effect as an index of convergent validity is problematic because it indicates that individual differences account for variation in observations, collapsing across traits and methods. This is conceptually different from the original notion of convergent validity, reflected in the correlations between different methods measuring a single construct. Finally, the ANOVA yields only omnibus information about trait and method effect. The approach precludes the exploration of correlations among traits, among methods, and between traits and methods.

Traditional MTMM-Confirmatory Factor Analysis (CFA) Model

The traditional MTMM-confirmatory factor analysis (see **Factor Analysis: Confirmatory**) model [7] uses covariance structure modeling to estimate a latent factor model in which each measure reflects a trait factor, a method factor, and a unique factor (i.e., random measurement and systematic measurement error specific to that measure). This model implies that measures assessing different constructs but employing a common method will be correlated because

of a shared method of measurement, and measures assessing the same construct but employing different methods will correlate because of a common underlying trait factor. The model also posits that trait factors are intercorrelated and that method factors are intercorrelated. High discriminant validity is reflected by weak correlations among trait factors. High convergent validity is reflected by large trait loadings and weak method factor loadings. Convergent validity is also improved when the variances in unique factors are small.

The traditional MTMM-CFA provides a parsimonious representation of MTMM data. Its assumptions are relatively explicit, and for the most part, intuitively follow from the original conceptualization of MTMM designs. Unfortunately, this approach routinely encounters computational difficulties in the form of improper solutions. The reasons for this problem are not entirely understood but might involve statistical or empirical identification problems. There are also certain ambiguities in the assumptions of this model that have generally gone unrecognized. For example, although the model assumes that traits and method effects are additive, interactions are possible [4, 15]. Moreover, the model actually allows for two potentially competing types of trait-method interactions. A hierarchical version of this model has been proposed [12]. This version has potential advantages over the first-order model in that it may be less susceptible to problems related to empirical identification, but it also suffers from some of the same limitations such as including competing types of trait-method interactions [15].

Restricted Versions of the Traditional CFA Model

In an effort to take advantage of the strengths of CFA while avoiding computational problems, some researchers [1, 10, 13] have proposed imposing constraints on the traditional MTMM-CFA model, thereby reducing the number of model parameters. For example, one may constrain the factor loadings from each method factor to the observed variables measured with that method to be equal to 1, and constrain the correlations between method factors to be zero.

By imposing constraints, the computational difficulties that arise from underidentification may be remedied. However, these constraints require

assumptions that are often unrealistic. In addition, the imposition of constraints reduces the amount of information provided by the model. For example, restrictions may preclude investigating correlations among method factors or which observed variables a particular trait most strongly influences.

Correlated Uniqueness Model

In this model [8, 11], only traits are represented as latent constructs. The influence of methods is represented in correlated unique variances for measures that share a common method. Thus, the unique variances in this model represent three sources of variability in measures: random error of measurement, specific factors, and method factors. Because both random error and specific factors are by definition uncorrelated, correlations among unique variances are attributable to a shared method of measurement. In this model, traits are permitted to correlate, but method factors are implied to be uncorrelated. Low correlations among traits indicate discriminant validity, and high convergent validity is represented by strong trait factor loadings. Method effects are gauged by the magnitude of the correlations among unique variances, with weak correlations implying greater convergent validity.

One advantage of this model is that it is less susceptible to computational difficulties. However, this model is based on similar assumptions to the traditional MTMM-CFA model, and therefore, the potential for the same logical inconsistencies exist. Also, because method factors are not directly represented, the model is not well suited for addressing specific questions regarding method effects.

Covariance Component Analysis

The Covariance Component Analysis (CCA) model [16] (see **Covariance Structure Models**) is based on the main effects portion of a random effects analysis of variance (see **Fixed and Random Effects**), but is typically tested using covariance structure modeling. Although there are a number of ways to parameterize this model, the Browne [3] parameterization is probably the most useful. In this parameterization, trait and method factors are treated as deviations from a general response factor (i.e., a ‘G’ factor). The scale of the latent variables is set by constraining the variance of the ‘G’ factor to 1.00.

Trait and method factors are represented by ‘Trait-deviation’ and ‘Method-deviation’ factors, and as such, the number of factors representing methods or traits is one less than the number of methods or traits included in the matrix. Trait deviations are permitted to correlate with each other but not with method deviations and vice versa. Neither trait nor method deviations correlate with the general response factor. Finally, a latent variable influencing each observed variable is specified. Random measurement error is incorporated into the model through error terms influencing each of the latent variables associated with each measured variable.

Unfortunately, even this parameterization does not provide immediately useful estimates, due to the fact that estimates for the traits and methods sum to zero. Thus, it is necessary to add ‘G’ separately to the trait and method deviations so that the correlation matrix among traits and the correlation matrix among methods can be computed. These matrices are then used to determine discriminant and convergent validity. Low correlations among traits imply discriminant validity. Convergent validity is supported by strong positive correlations among method factors, which indicate that the methods produce similar patterns of responses. The CCA also provides estimates of communalities for the measured variables.

The CCA model has advantages over many other models because it is a truly **additive model** and thus does not allow for the conceptual ambiguities that can occur in many CFA models. Furthermore, the matrices produced efficiently summarize properties of the data. Importantly, the CCA approach does not have the computational problems characteristic of the traditional MTMM-CFA model. A potential limitation is that it provides relatively little information about the performance of individual observed variables.

Composite Direct Product Model

Traditionally, MTMM researchers have assumed that trait and method factors combine in an additive fashion to influence measures. However, interactions among trait and method factors may exist, thus making additive models inappropriate for some data sets. The Composite Direct Product (CDP) model [2] was developed to deal with interactions between traits and

methods. In this model, each measure is assumed to be a function of a multiplicative combination of the trait and the method underlying that measure. Each measure is also assumed to be influenced by a unique factor. The model allows for correlations among trait factors and correlations among method factors. No correlations are permitted between method factors and trait factors. High discriminant validity is reflected in weak correlations among traits. As with the CCA, high correlations among methods suggest high convergent validity. Estimates of communalities provide information about the influence of random measurement error and specific factors.

One strength of the model is that its parameters can be related quite directly to the questions of interest in MTMM research. The CDP improves upon the traditional MTMM-CFA model and its variants in that it does not suffer from the conceptual ambiguities of these approaches. Moreover, the CDP is less susceptible to computational problems. Applications of the CDP have suggested that it usually produces satisfactory fit and sensible parameter estimates. Interestingly, when applied to data sets for which there is little evidence of trait-method interactions, the CDP model often provides similar fit and parameter estimates to the CCA model. However, the CDP model appears to sometimes perform better than the CCA model for data sets in which there is evidence of trait-method interactions. As with the CCA approach, the model provides relatively little information about the performance of individual measures.

Conclusions

When analyzing MTMM data, it seems most sensible to begin with a consideration of the four properties of the MTMM correlation matrix originally proposed by Campbell and Fiske [5]. If the properties of the original MTMM matrix are consistent with the results of more formal analyses, researchers can be more confident in the inferences they draw from those results. In addition, the assumptions of more formal analytical methods (e.g., do traits and methods combine in an additive or multiplicative manner?) can be evaluated by examining the original MTMM matrix [15]. Researchers should then consider what formal statistical analyses are most appropriate. Many approaches have serious limitations. The CCA and the CDP probably have the strongest conceptual

foundations and the fewest practical limitations. Of these two, the CDP has the advantages of being easier to implement and perhaps more robust to violations of its underlying assumptions about the nature of trait-method effects. However, until the contexts in which the CDP and CCA differ are better understood, it might be useful to supplement initial CDP analyses with a CCA analysis using Browne's [3] parameterization. If the results are similar, one can be confident that the conclusions hold under assumptions of either additive or multiplicative trait-method effects. If they are found to substantially differ, then it is necessary to carefully evaluate the plausibility of each model in light of conceptual and empirical considerations.

Multivariate Analysis: Bayesian

Multivariate Bayesian analysis is that branch of statistics that uses *Bayes' theorem* (see **Bayesian Belief Networks**) to make inferences about several, generally correlated, unobservable and unknown quantities. The unknown quantities may index probability distributions; they may be hypotheses or propositions; or they may be probabilities themselves (see **Bayesian Statistics**). Such procedures have widespread applications in the behavioral sciences.

Bayes' Theorem

In Bayesian analysis, an unknown quantity is assigned a probability distribution, to represent one's degree-of-belief about the unknown quantity. This degree-of-belief is then modified via Bayes' theorem, as new information becomes available through observational data, experience, or new theory. Multivariate Bayesian inference is based on Bayes' theorem for correlated random variables.

Symbolically, let Θ denote a collection (vector) of k unobservable jointly continuous random variables, and $\mathbf{X}$ a collection of N observable, p -dimensional jointly continuous random vectors. Let $f(\cdot)$, $g(\cdot)$, and $h(\cdot)$ denote probability density functions of their arguments. (Lowercase letters will be used to represent observed values of the random variables designated by uppercase letters. Sometimes, for convenience, we will use lowercase letters throughout. We use boldface to designate vectors and matrices.) Bayes theorem for continuous $\mathbf{X}$ and continuous Θ asserts that

$$h(\theta|\mathbf{x}) = \left(\frac{1}{Q} \right) f(\mathbf{x}|\theta)g(\theta), \quad (1)$$

where θ and $\mathbf{x}$ denote values of Θ and $\mathbf{X}$, respectively, and Q denotes a one-dimensional constant (possibly depending on $\mathbf{x}$, but not on θ), which is given by

$$Q = \int f(\mathbf{x}|\theta)g(\theta)d\theta. \quad (2)$$

The integration is taken over all possible values in k -dimensional space, and the notation $f(\mathbf{x}|\theta)$

should be understood to mean the density of the conditional distribution of $\mathbf{X}$, given $\Theta = \theta$. $f(\mathbf{x}|\theta)$ is the joint probability density function for $\mathbf{X}|\Theta = \theta$. When it is viewed as a function of θ , it is called the *likelihood function* (see **Maximum Likelihood Estimation**). When $\mathbf{X}$ and/or Θ are discrete, we replace integrals by sums, and probability density functions by probability mass functions. $g(\theta)$ is the *prior density* of Θ , since it is the probability density of Θ prior to having observed $\mathbf{X}$. Note that the prior density should not depend in any way upon the current data set, although it certainly could, and often does depend upon earlier-obtained data sets. If the prior were permitted to depend upon the current data set, using Bayes' theorem in this inappropriate way would violate the laws of probability. $h(\theta|\mathbf{x})$ is the *posterior density* of Θ , since it is the distribution of Θ 'subsequent' to having observed $\mathbf{X} = \mathbf{x}$.

Bayesian inference in multivariate distributions is based on the posterior distribution of the unobservable random variables, Θ , given the observable data (the unobservable random variable may be a vector or a matrix). A Bayesian estimator of θ is generally taken to be a measure of location of the marginal posterior distribution of Θ , such as its mean, median, or mode. To obtain the marginal posterior density of Θ given the data, it is often necessary to integrate the joint posterior density over spaces of other unobservable random variables that are jointly distributed with θ . For example, to determine the marginal posterior density of a mean vector θ , given data $\mathbf{x}$, from the joint posterior density of a mean vector θ and a covariance matrix Σ , given $\mathbf{x}$, we must integrate the joint posterior density of (θ, Σ) , given $\mathbf{x}$ over all elements of Σ that make it positive definite.

Bayesian Inferences

Bayesian confidence regions (called *credibility regions*) are obtainable for any preassigned level of credibility directly from the cumulative distribution function of the posterior distribution. We make a distinction here between 'credibility' and 'confidence' that is fundamental, and not just a simple choice of alternative words.

The *credibility region* is a probability region for the unknown, unobservable vector or matrix, conditional on the specific value of the observables that happened to have been observed in this instance,

2 Multivariate Analysis: Bayesian

regardless of what values of the observables might be observed in other instances (the region is based upon $P\{\Theta|\mathbf{X}\}$). For example, Ω denotes a 95% credibility region for $\Theta|\mathbf{X}$ if

$$P\{\Theta \in \Omega|\mathbf{X}\} = 95\%. \quad (3)$$

The *confidence region*, by contrast, is obtained from a probability statement about the observable variables, conditional on the unobservable ones. So it really represents a region based upon the distribution of $\mathbf{X}$ as to where the observables are likely to be, rather than where the unobservables are likely to be (the region is based upon $P\{\mathbf{X}|\theta\}$). (For more details, see **Confidence Intervals**).

When nonuniform, proper prior distributions are used, the resulting credibility and confidence regions will generally be quite different from one another.

Predictions about a data vector(s) or matrix not yet observed are carried out by averaging the likelihood for the future observation vector(s) or matrix over the best information we have about the indexing parameters of its distribution, namely, the posterior distribution of the indexing parameters, given the data already observed.

Hypothesis testing may be carried out by comparing the posterior probabilities of all competing hypotheses, given all data observed, and selecting the hypothesis with the largest posterior probability. These notions are identical with those in univariate Bayesian analysis. In multivariate Bayesian analysis, however, in order to make posterior inferences about a given hypothesis, conditional upon the observable data, it is generally necessary to integrate over all the components of Θ .

Multivariate Prior Distributions

The process of developing a prior distribution to express the beliefs of the analyst about the likely values of a collection of unobservables is called *multivariate subjective probability assessment*. None of the variables in a collection of unobservables, Θ , is ever known. The multivariate prior probability density function, $g(\theta)$ for continuous θ (or its counterpart, the prior probability mass function for discrete θ), is used to denote the degrees of belief the analyst holds about θ . The parameters that index the prior distribution are called *hyperparameters*.

Table 1 Prior distribution $g(\theta_1, \theta_2)$

		θ_2	
		0	1
θ_1	0	0.2	0.1
	1	0.3	0.4

For example, suppose a vector mean θ is bivariate ($k = 2$), so that there are two unobservable, one-dimensional random variables Θ_1 and Θ_2 . Suppose further (for simplicity) that Θ_1 and Θ_2 are discrete random variables, and let $g(\theta_1, \theta_2)$ denote the joint probability mass function for $\Theta = (\Theta_1, \Theta_2)'$.

Suppose Θ_1 and Θ_2 can each assume only two values, 0 and 1, and the analyst believes the probable values to be given by those in Table 1.

Thus, for example, the analyst believes that the chances that Θ_1 and Θ_2 are both 1 is 0.4, that is,

$$P\{\Theta_1 = 1, \Theta_2 = 1\} = g(1, 1) = 0.4. \quad (4)$$

Note that this bivariate prior distribution represents the beliefs of the analyst, and need not correspond to the beliefs of anyone else, neither any individual, nor any group. Other individuals may feel quite differently about Θ .

In some situations, the analyst does not feel at all knowledgeable about the likely values of unknown, unobservable variables. In such cases, he/she will probably resort to using a ‘vague’ (sometimes called ‘diffuse’ or ‘noninformative’) prior distribution. Let Θ denote a collection of k continuous, unknown variables, each defined on $(-\infty, \infty)$. $g(\theta)$ is a vague prior density for Θ if the elements of Θ are mutually independent, and if the probability mass of each variable is diffused evenly over all possible values. We write the (improper) prior density for Θ as

$$g(\theta) \propto \text{constant},$$

where $\propto$ denotes proportionality. Note that while this density characterization corresponds in form to the density of a uniform distribution, the fact that this uniform distribution must be defined over the entire real line means that the distribution is improper (it does not integrate to one) except in the case where the components of θ are defined on a finite interval. While prior distributions may sometimes be

improper, the corresponding posteriors must always be proper.

The vague prior for positive definite random variables is quite different. If Σ denotes a k -dimensional square and symmetric positive definite matrix of variances and covariances, a vague (improper) prior for Σ is given by (see [6]):

$$g(\Sigma) \propto |\Sigma|^{-(k+1)/2}$$

where $|\Sigma|$ denotes the determinant of the matrix Σ . Sometimes *natural conjugate* or other families of multivariate prior distributions are used (see, e.g., [10,11]).

Multivariate prior distributions are often difficult to assess because of the complexities of thinking in many dimensions simultaneously, and also because the number of parameters to assess is so much greater than in the univariate case. For some methods that have been proposed for assessing multivariate prior distributions, see, for example, [7, 10] or [11, Chapter 5].

Numerical Methods

Numerical methods are of fundamental importance in Bayesian multivariate analysis. They are used for evaluating and approximating the normalizing constants of multivariate posterior densities, for finding marginal densities, for calculating moments and other functions of marginal densities, for sampling from multivariate posterior densities, and for many other needs associated with multivariate Bayesian statistical inference. The principal methods currently in use are computer-intensive: Markov Chain Monte Carlo (MCMC) methods (see **Markov Chain Monte Carlo and Bayesian Statistics**) and the *Metropolis-Hastings Algorithm* ([1–4, 8, 9], [11, Chapter 6], and [16, 17]).

An Example

The data for this illustrative example first appeared in Kendall [8]. There are 48 applicants for a certain job and they have been scored on 15 variables regarding their acceptability. The variables are as shown in Table 2.

The question is: Is there an underlying subset of factors (of dimension less than 15) that

Table 2 Data reproduced from Kendall, M. *Multivariate Analysis*, 2nd Edition, Griffin Publisher, Charles, 34

1	Form of letter application
2	Appearance
3	Academic ability
4	Likability
5	Self-confidence
6	Lucidity
7	Honesty
8	Salesmanship
9	Experience
10	Drive
11	Ambition
12	Grasp
13	Potential
14	Keenness to join
15	Suitability

explain the variation observed in the 15-dimensional scores? If so, the applicants could then be compared more easily.

Adopt the Bayesian **factor analysis** model

$$\mathbf{x}_j = \underset{(p \times m)}{\mathbf{\Lambda}} \underset{(m \times 1)}{\mathbf{f}_j} + \underset{(p \times 1)}{\boldsymbol{\epsilon}_j} \quad j = 1, \dots, N, \quad m < p. \quad (5)$$

Here, $\mathbf{\Lambda}$ denotes the (unobservable) factor-loading matrix; $\mathbf{f}_j$ denotes the (unobservable) factor score vector for subject j , with $\mathbf{F}' \equiv (\mathbf{f}_1, \dots, \mathbf{f}_N)$; the $\boldsymbol{\epsilon}_j$'s are assumed to be (unobservable) disturbance vectors, mutually uncorrelated and normally distributed as $N(\mathbf{0}, \Psi)$, where Ψ is permitted to be a general, symmetric, positive definite matrix, although $E(\Psi)$ is assumed to be a diagonal matrix. The dimension of the problem is p ; in this example, $p = 15$; m denotes the number of underlying factors (in this example, $m = 4$, but it is generally unknown); and N denotes the number of subjects; in this example, $N = 48$. There are three unknown matrix parameters: $(\mathbf{\Lambda}, \mathbf{F}, \Psi)$. Assume *a priori* that

$$g(\mathbf{\Lambda}, \mathbf{F}, \Psi) = g_1(\mathbf{\Lambda}|\Psi)g_2(\Psi)g_3(\mathbf{F}), \quad (6)$$

where the g 's denote prior probability densities of their respective arguments. Thus, $\mathbf{F}$ is assumed to be *a priori* independent of $(\mathbf{\Lambda}, \Psi)$. Adopt, respectively, the normal and inverted Wishart prior densities:

$$g_1(\mathbf{\Lambda}|\Psi) \propto |\Psi|^{-0.5m}$$

$$\times \exp\{(-0.5)\text{tr}[\Psi^{-1}(\Lambda - \Lambda_0)\mathbf{H}(\Lambda - \Lambda_0)']\}$$

$$g_2(\Psi) \propto |\Psi|^{-0.5\nu} \exp\{-0.5\text{tr}(\Psi^{-1}\mathbf{B})\},$$

where ‘tr’ denotes the matrix trace operation. There are many prior densities for $\mathbf{F}$ that might be used (see [10]). For simplicity, adopt the vague prior density

$$g_3(\mathbf{F}) \propto \text{constant}.$$

The quantities $\mathbf{H}$, Λ_0 , ν , $\mathbf{B}$ are hyperparameters that must be assessed. A model with four factors is postulated on the basis of having carried out a principal components analysis and having found that four factors accounted for 81.5% of the variance. This is therefore the first guess for m .

Adopt the simple hyperparameter structure: $\mathbf{H} = n_0\mathbf{I}_m$, for some preassigned scalar n_0 , and $\mathbf{I}_m$ denotes the identity matrix of order m . In this example, take $\mathbf{H} = 10\mathbf{I}_4$, $\mathbf{B} = 0.2\mathbf{I}_{15}$, and $\nu = 33$. On the basis of the underlying beliefs, the following transposed location hyperparameter, Λ'_0 , for the factor-loading matrix, Λ was constructed:

$$\Lambda'_0 = \begin{pmatrix} 0.0 & 0.0 & 0.0 & 0.0 & 0.7 & 0.7 & 0.0 & 0.7 & 0.0 & 0.7 & 0.7 & 0.7 & 0.7 & 0.0 & 0.0 \\ 0.0 & 0.0 & 0.7 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 \\ 0.7 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.7 & 0.0 & 0.0 & 0.0 & 0.0 & 0.7 \\ 0.0 & 0.0 & 0.0 & 0.7 & 0.0 & 0.0 & 0.7 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 \\ 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10 & 11 & 12 & 13 & 14 & 15 \end{pmatrix} \quad (7)$$

The four underlying factors are found as linear combinations of the original 15 variables. (See [11, Chapter 15], [12, 13], for additional details.) Factor scores and credibility intervals for the factor scores are given in [11, Chapter 15].

It is shown in [12] how the number of underlying factors may be selected by maximizing the posterior probability over m , the number of factors. An empirical Bayes estimation approach is used in [14] to assess the hyperparameters in the model. Other proposals for assessing the hyperparameters may be found in [5] and [15].

Multivariate Analysis: Overview

Many social or behavioral studies lead to the collection of data in which more than one variable (feature, attribute) is measured on each sample member (individual, subject). This can happen either by design, where the variables have been chosen because they represent essential descriptors of the system under study, or because of expediency or economy, where the study has been either difficult or expensive to organize, so as much information as possible is collected once it is in progress. If p variables ($X_1, X_2, \dots, X_p$, say) have been measured on each of n sample individuals, then the resulting values can be displayed in a *data matrix* $\mathbf{X}$. Standard convention is that rows relate to sample individuals and columns to variables, so that $\mathbf{X}$ has n rows and p columns, and the element x_{ij} in the i th row and j th column is the value of the j th variable exhibited by the i th individual. For example, the data matrix in Table 1 gives the values of seven measurements in inches (chest, waist, hand, head, height, forearm, wrist) taken on each of 17 first-year university students.

In most cases, the rows of a data matrix will not be related in any way, as the values observed on

any one individual in a sample will not be influenced by the values of any other individual. This is obvious in the case of the students' measurements. However, since the whole set of variables is measured on *each* individual, the columns will be related to a greater or lesser extent. In the example above, tall students will tend to have large values for all the variables, while short ones will tend to have small values across the board. There is, therefore, correlation between any pair of variables, and a typical multivariate data matrix will have a possibly complex set of interdependencies linking the columns. This means that it is dangerous to analyze the variables individually if general conclusions are desired about the overall system. Rather, techniques that analyze the whole ensemble of variables are needed, and this is the province of multivariate analysis.

Multivariate methods have had a slightly curious genesis and development. The earliest work, dating from the end of the nineteenth century, was rooted in practical problems arising from social and educational research, specifically in the disentangling of factors underlying correlated Intelligence Quotient (IQ) tests. This focus gradually widened and led to many developments in the first half of the twentieth century, but because computational aids were very limited, these developments were primarily mathematical. Indeed, multivariate research at that time might almost be viewed as a branch of linear algebra, and practical applications were very limited as a consequence of the formidable computational requirements attaching to most techniques. However, the advent and rapid development of electronic computers in the second half of the twentieth century removed these barriers. The first effect was an expansion in the practical use of established techniques, which was then followed by renewed interest in development of new techniques. Inevitably, this development became more and more dependent on sophisticated computational support, and, as the century drew to a close, the research emphasis had shifted perceptibly from mathematics to computer science. Currently, new results in multivariate analysis are reported as readily in sociological, psychological, biological, or computer science journals as they are in the more traditional statistical, mathematical, or engineering ones.

The general heading 'multivariate analysis' covers a great variety of different techniques that can be grouped together for ease of description in various

Table 1 Data matrix representing seven measures on each of 17 students

Row	Chest	Waist	Hand	Head	Height	Arm	Wrist

ways. Different authors have different preferences, but, for the purpose of this necessarily brief survey, I will consider them under four headings: Visualization and Description; Extrapolation and Inference; Discrimination and Classification; Modeling and Explanation. I will then end the article by briefly surveying current trends and developments.

Visualization and Description

A data matrix contains a lot of information, often of quite complex nature. Large-scale investigations or surveys may contain thousands of individuals and hundreds of variables, in which case assimilation of the raw data is a hopeless task. Even in a relatively small dataset, such as that of the university students above, the interrelationships among the variables make direct assimilation of the numbers difficult. As a first step towards analysis, a judicious pictorial representation may help to uncover patterns, identify unusual observations, suggest relationships between variables, and indicate whether assumptions made by formal techniques are reasonable or not. So, effort has been expended in devising ways of representing multivariate data with these purposes in mind, and several broad classes of descriptive techniques can be identified.

The simplest idea derives from the *pictogram* and is a method for directly representing a multivariate sample in two dimensions (so that it can be drawn on a sheet of paper or shown on a computer screen). The aim here is to represent each individual in the sample by a single object (such as a box, a star, a tree, or a face) using the values of the variables for that individual to determine the size or features of the object (see **Star and Profile Plots**). So, for example, each variable might be associated with a branch of a tree, and the value of the variable determines its length, or each variable is associated with a facial feature, and the value determines either its size or its shape. The idea is simple and appealing, and the methods can be applied whether the data are quantitative, qualitative, or a mixture of both, but the limitations are obvious: difficulties in relating individuals and variables or directly comparing the latter across individuals, inability to cope with large samples, and no scope for developing any interpretations or analyses from the pictures. Andrews' curves [2], where each individual is represented by a Fourier curve over a range

of values, introduces more quantitative possibilities, but limitations still exist.

A more fruitful line of approach when the data are quantitative is to imagine the $n \times p$ data matrix as being represented by n points in p dimensions. Each variable corresponds to a dimension and each individual to a point, the coordinates of each point on p orthogonal axes being given by the values of the p variables for the corresponding individual. Of course, if p is greater than 2, then such a configuration cannot be seen directly and must somehow be approximated. The **scatterplot** has long been a powerful method of data display for bivariate data, and computer graphics now offer the user a large number of possibilities. The basic building block is the **scatterplot matrix**, in which the scatterplots for all $p(p-1)$ ordered pairs of variables are obtained and arranged in matrix fashion (so that each marginal scale applies to $p-1$ plots). The separate plots can be linked by *tagging* (where individual points are tagged so that they can be identified in each plot), *brushing* (where sets of points can either be highlighted in, or deleted from, each plot), and *painting* (where color is used to distinguish grouping or overplotting in the diagrams). The development of such depth-cueing devices as *kinematic* and *stereoscopic* displays has led to **three-dimensional scatterplot** depiction, and modern software packages now routinely include such facilities as dynamic rotations of three-dimensional scatterplots, tourplots, and rocking rotations (i.e., ones with limited angular displacements). Moreover, window-based systems allow the graphics to be displayed in multiple windows that are linked by their observations and/or their variables. For details, see [25] or [26].

Despite their ingenuity and technical sophistication, the above displays are still limited to pairs or triples of variables and stop short at pure visualization. To encompass all variables simultaneously, and to allow the possibility of substantive interpretation, we must move on to *projection* techniques. The idea here is to find a low-dimensional subspace of the p -dimensional space into which the n points can be projected; for a sufficiently low dimensionality (2 or 3), the points can then be plotted and any patterns in the data easily discerned. The problem is to find a projection that minimizes the distortion caused by approximation in a lower dimensionality. However, what is meant by 'minimizing distortion' will depend on what features of the data are considered to

be important; many different projection methods now exist, each highlighting different aspects of the data.

The oldest such technique, dating back to the turn of the twentieth century, is **principal component analysis** (PCA) [17]. This has many different characterizations, but the two most common ones are as the subspace into which the points are orthogonally projected with least sum of squared (perpendicular) displacements, or, equivalently, as the subspace which maximizes the total variance among the coordinates of the points. The latter characterization identifies the subspace as the one with maximum inter-point scatter, so is the one in which the overall configuration of points is best viewed to detect interesting patterns. The technique has various side benefits: it has an analytical solution from which configurations in any chosen dimensionality can be obtained, and the chosen subspace is defined by a set of orthogonal linear combinations or contrasts among the original variables. The latter property enables directions of scatter to be substantively interpreted, or *reified*, which adds power to any analysis.

If the data have arisen from a number of *a priori* groups, and one objective in data visualization is to highlight group differences, then *canonical variate analysis* (CVA) [6] is the appropriate technique to use (see **Canonical Correlation Analysis; Discriminant Analysis**). This has similarities to PCA in that the requisite subspaces are again defined by linear combinations or contrasts of the original variables, and the solution is also obtained analytically for any dimensionality, but the projections in this case are not orthogonal, and, hence, interpretation is a little harder. If other facets of the data are to be highlighted (e.g., subspaces in which either **skewness** or **kurtosis** is maximized, or subspaces in which the data are as nonnormal as possible), then computational searches rather than analytical solutions must be undertaken. All such problems fall into the category known as **projection pursuit** [18]. Moreover, dimensionality reduction can be optimally linked to some other statistical techniques in this way, as with *projection pursuit regression*.

The above projection methods require quantitative data, in order for the underlying model of n points in p dimensions to be realizable. So what can be done if qualitative data (such as presence/absence of attributes, or categories like different colors) are present? Here, we can link the concepts of *dissimilarity* and *distance* to enable us to *construct* a

low-dimensional representation of the data for visualization and interpretation (see **Proximity Measures**). There are many ways of measuring the *dissimilarity* between two individuals [15]. If we choose a suitable measure appropriate for our data, then we can compute a *dissimilarity matrix* that gives the dissimilarity between every pair of individuals in the sample. **Multidimensional scaling** is a suite of techniques that represents sample individuals by points in low-dimensional space in such a way that the distance between any two points approximates as closely as possible the dissimilarity between the corresponding pair of individuals. If the approximation is in terms of exact values of distance/dissimilarity, then *metric* multidimensional scaling provides an analytical solution along similar lines to PCA, while if the approximation is between the rank orders of the dissimilarities and distances, then *nonmetric* multidimensional scaling provides a computational solution along the lines of projection pursuit. Many other variants of multidimensional scaling now also exist [5].

The above are the most commonly used multivariate visualization techniques in practical applications. They are essentially *linear* techniques, in that they deal with linear combinations of variables and involve linear algebra for their solution. Various *non-linear* techniques have recently been developed [13], but are only slowly finding their way into general use.

Extrapolation and Inference

Frequently, a multivariate data set comes either as a sample from some single population of interest or as a collection of samples from two or more populations of interest. The main focus then may not be on the sample data *per se*, but rather on extrapolating from the sample(s) to the population(s) of interest, that is, on drawing *inferences* about the population(s).

For example, the data on university students given above is actually a subset of a larger collection, in which the same measurements were taken on samples of both male and female students from each of a number of different institutions. Interest may then center on determining whether there are any differences overall, either between genders or institutions, in terms of the features measured for the samples.

In order to make inferences about populations, it is necessary to postulate probability models for these

4 Multivariate Analysis: Overview

populations, and then to couch the inferences in terms of statements about the parameters of these models. In classical (frequentist) inference, the traditional ways of doing this are through either estimation (whether point or interval) of the parameters or testing hypotheses about them. In Bayesian inference, all statements are channeled through the posterior distribution of the model parameters (*see Bayesian Statistics*).

Taking classical methods first, the underlying population model for quantitative multivariate data has long been the multivariate normal distribution (*see Catalogue of Probability Density Functions*), although some attention has also been paid in recent years to the class of *elliptically contoured distributions* [11]. The multivariate normal distribution is characterized completely by its mean vector and dispersion matrix, and most traditional methods of estimation (such as **maximum likelihood**, least squares, or invariance) lead to the sample mean vector and some constant times the sample covariance matrix as the estimates of the corresponding population parameters. Moreover, distribution theory easily leads to confidence regions, at least for the population mean vector. So, for estimation, multivariate results appear to be ‘obvious’ generalizations of familiar univariate quantities.

Hypothesis testing is not so straightforward, however. Early results were derived by researchers who sought ‘intuitive’ generalizations of univariate test statistics, such as Hotelling’s T^2 statistics for one- and two-sample tests of means as generalizations of the familiar one- and two-sample t statistics in univariate theory. It soon became evident that this avenue afforded limited prospects, however, so a more structured approach was necessary. Several general methods of test construction thus evolved, and the most common of these were the likelihood ratio, the union-intersection, and the invariant test procedures. An unfortunate side effect of this multiplicity is that each approach in general leads to a different test statistic in any single situation, the only exceptions being those that lead to the T^2 statistics mentioned above. Typically, the likelihood ratio approach produces test statistics involving products of all **eigenvalues** of particular matrices, the union-intersection approach produces test statistics involving just the largest eigenvalue of such matrices, and other approaches frequently produce test statistics involving the sum of the eigenvalues; in

statistical software, the product statistic is generally termed *Wilks’ lambda*, the largest eigenvalue is usually referred to as *Roy’s largest root*, while the sum statistic is either *Pillai’s trace* or *Hotelling–Lawley’s trace* (for more details *see Multivariate Analysis of Variance*). Tables of critical values exist [24] for conducting significance tests with these statistics, but it should be noted that the different statistics test for different departures from the null hypothesis, and so, in any given situation, may provide contradictory inferences.

One- or two-sample tests can be derived for most situations by using one of the above approaches, and most standard textbooks on multivariate analysis quote the relevant statistics and associated distribution theory. When there are more than two groups, or if there is a more complex design structure on the data (such as a factorial cross-classification, for example), then the *multivariate* analysis of variance (MANOVA) provides the natural analog of *univariate analysis of variance* (ANOVA). The calculations for any particular MANOVA design are exactly the same as for the corresponding ANOVA design, except that they are carried out for each separate variable and then for each pair of variables, and the results are collected together into matrices. All resulting ANOVA sums of squares are thereby translated into MANOVA sums of squares and product matrices, and in place of a ratio of mean squares for any particular ANOVA effect, we have a product of one matrix with the inverse of another. Test statistics are then based on the eigenvalues of these matrices, using one of the four variants described above. Moreover, if any effect proves to be significant, then *canonical variate analysis* (also referred to as *descriptive discriminant analysis*; *see Discriminant Analysis*) can be used to investigate the reasons for the significance.

Most classical multivariate tests require the data to come from either the multivariate normal or an elliptically contoured distribution for the theory to be valid and for the resulting tests to have good properties. This is sometimes a considerable restriction (*see Multivariate Normality Tests*). However, the computing revolution that took place in the last quarter of the twentieth century means that very heavy computing can now be undertaken for even the most routine analysis. This has opened up the possibility of conducting inference computationally rather than mathematically, and such computer-intensive procedures as

permutation testing, **bootstrapping**, and **jackknifing** [7] now form a routine approach to inference.

Bayesian inference requires the specification of a prior distribution for the unknown parameters, and this prior distribution is converted into a posterior distribution by multiplying it by the likelihood of the data. Inference is then conducted with reference to this posterior distribution, perhaps after integrating out those parameters in which there is no interest. For many years, **multivariate Bayesian inference** was hampered by the complicated multidimensional integrals that had to be effected during the derivation of the posterior distribution, and older textbooks restricted attention either to a small set of conjugate prior distributions or to the case of prior uncertainty. Since the development of **Markov Chain Monte Carlo** (MCMC) methods in the early 1990s, however, the area has been opened up considerably, and, now, virtually any prior distribution can be handled numerically using the software package BUGS.

Discrimination and Classification

Whenever there are *a priori* groups in a data set, for example the genders or the institutions for the measurements on university students, the above methods give a mechanism for deciding whether the populations from which the groups came are different or not. If the populations are different, then further questions become relevant: How can we best characterize the differences? How can we best allocate a future unidentified individual to his or her correct group? The first of these questions concerns *discrimination* between the groups, while the second concerns *classification* of (future) individuals to the specified groups. Such questions have assumed great currency, particularly in such areas as health, where it is important to be able to distinguish between, and to correctly allocate individuals to, groups such as disease classes. This topic is a genuinely multivariate one, as intuitively one feels that increasing the number of variables on each individual should increase the ability to discriminate between groups (see **Discriminant Analysis**). Unfortunately, however, the word ‘classification’ has also been used in a rather different context, namely, in the sense of partitioning a collection of individuals into distinct classes. This usage has come down from biological/taxonomic applications, and in the statistical literature, has been distinguished

from allocation by calling it *clustering*. Another way of distinguishing the two usages, popularized in the **pattern recognition** and computer science literature, is to refer to the allocation usage as *supervised classification*, and to the partitioning usage as *unsupervised classification*. This is the nomenclature that we will adopt in the present overview.

At the heart of supervised classification is a function or set of functions of the measured variables. For simplicity, we will refer just to a single function $f(\mathbf{x})$. If distinguishing the groups is the prime purpose, then $f(\mathbf{x})$ is usually termed a *discriminant function*, while if allocation of individuals to groups is the intended usage, it is termed a *classification function* or *classifier*. The first appearance of such a quantity in the literature was the now famous *linear discriminant function* between two groups, derived by **R.A. Fisher** in 1935 on purely intuitive grounds. Subsequently, Welch demonstrated in 1938 that it formed an optimal classifier into one of two multivariate normal populations that shared the same dispersion matrix, while Anderson provided the sample version in 1951.

In the years since then, a great variety of discriminant functions and classifiers have been suggested. Relaxing the assumption of common dispersion matrices in normal populations leads to a *quadratic discriminant function*; eschewing distributional assumptions altogether requires a *non-parametric discriminant function*; estimating probabilities of class membership for classification purposes can be done via *logistic discriminant functions* (see **Logistic Regression**); producing a classifier by means of a sequence of decisions taken on individual variables results in a *tree-based classifier* (see **Classification and Regression Trees**); while recent years have seen the development of a variety of computer-intensive classifiers using **neural networks**, *regularized discriminant functions*, and *radial basis functions*. Bayesian approaches to parametric discriminant analysis were hampered in the early days for the same reasons as already described above, but MCMC procedures are now beginning to be applied in the classification field also. With so many potential classifiers to choose from, ways of assessing their performance is an important consideration. There are various possible measures of performance [16], but the most common one in practical use is the *error rate* associated with a classifier (see **Misclassification Rates**). Another focus of interest

in supervised classification is the question of *variable selection*; in many problems, only a restricted number of variables provide genuine discriminatory information between groups, while the other variables essentially only contribute noise. Classification performance, as well as economy of future measurement, can, therefore, be enhanced by finding this ‘effective’ subset of variables, and much research has, therefore, been conducted into variable selection procedures. In the Bayesian approach, variable selection requires the use of reversible jump MCMC. Full technical details of all these aspects can be found in [8, 16, 22].

Unsupervised classification has an even longer history than the supervised variety, dating back essentially to the numerical taxonomy and biological classification of the nineteenth century. It has developed as a series of ad-hoc advances rather than as a systematic field, and can now be characterized in terms of several groups of loosely connected methods. The oldest set of methods are the *hierarchical clustering* methods in which the sample of n individuals is either progressively grouped, starting with separate groups for each individual and finishing with a single group containing all individuals by fusing two existing groups at each stage, or progressively splitting from a single group containing all individuals down to n groups, each containing a single individual, by dividing an existing group into two at each stage. Both approaches result in a ‘family tree’ structure, showing how individuals either successively fuse together or split apart, and this structure fitted well into the biological classification schemes that were its genesis (see **Hierarchical Clustering**). However, over the years, many different criteria have been proposed for fusing or splitting groups, so now the class of hierarchical methods is a very large one. By contrast with hierarchical methods are the *optimization* methods of clustering, in which the sample of n individuals is partitioned into a prespecified number g of groups in such a way as to optimize some numerical criterion that quantifies the two desirable features of *internal cohesion* within groups and *separability* between groups (see **k-means Analysis**). As can be imagined, many different criteria have been proposed to quantify these features, so there are also many such clustering methods. Moreover, each of these methods often requires formidable computing resources if n is large and needs to be repeated for different values of g if an optimum number of groups is also desired.

Other possible approaches to clustering involve probabilistic models for groups (*mode-splitting* or *mixture separation*; see **Model Based Cluster Analysis**) or *latent variable models* (see below). Further technical details may be found in [10, 14].

Modeling and Explanation

It has already been stressed that association between the variables is one of the chief characteristics of a multivariate data set. If the variables are quantitative, then the correlation coefficient is a familiar measure of the strength of association between two variables, while if the variables are categorical, then the data set can be summarized in a **contingency table** and the strength of association between the variables can be assessed through a chi square test using the chi square measure X^2 . If there are many variables in a data set, then there are potentially many associations between pairs of variables to consider. In the students’ measurements, for example, there are seven variables and, hence, 21 correlations to assess. With 20 variables, there will be 190 correlations, and the number rapidly escalates as the number of variables increases. The pairwise nature of these values means that many interrelationships exist among a set of such correlations, and these interrelationships must be disentangled if any sense is to be made of the overall situation.

One simple technique is to calculate **partial correlations** between specified variables when others are considered to be held fixed. This will help to determine whether an apparently high association between a pair of variables is genuine or has been induced by their mutual association with the other variables. Another simple technique is to treat correlation r as ‘similarity’ between two variables, in which case a measure such as $1 - r^2$ or $(1 - r)/2$ can be viewed as a ‘distance’ between them. Applying some form of multidimensional scaling to a resulting set of distances will then represent the variables as points on a low-dimensional graph and will show up groups of ‘similar’ variables as well as highlighting those variables that are very different from the rest. If variables are qualitative/categorical, then **correspondence analysis** is a technique for obtaining low-dimensional representations that highlight relationships, both between variables and between groups of individuals. Finally, if the variables have some

form of *a priori* grouping structure on them, then **canonical correlation analysis** will extract essential association between these groups from the detail of the whole correlation matrix.

However, if a deeper understanding is to be gained into the nature of a set of dependencies, possibly leading on to a substantive explanation of the system, then some form of underlying model must be introduced. This area forms arguably the oldest single strand of multivariate research, that of **latent variable** models. The origins date back to the pioneering work of **Spearman** and others in the field of educational testing at the start of the twentieth century, where empirical studies showed the presence of correlations between scores achieved by subjects over a range of different tests. Initial work attempted to explain these correlations by supposing that each score was made up of the subject's value on an underlying, unobservable, variable termed 'intelligence', plus a 'residual' specific to the individual subject and test. First results seemed promising, but it soon became evident that such a single-variable explanation was not sufficient. The natural extension was then to postulate a model in which a particular test score was made up of a combination of contributions from a *set* of unobservable underlying variables in addition to 'intelligence,' say 'numerical ability,' 'verbal facility,' 'memory,' and so on, plus a residual specific to the individual subject and test. If these underlying *factors* could account for the observed inter-test correlations, then they would provide a characterization of the system. Determination of number and type of factors, and extraction of the combinations appropriate to each test thus became known as **factor analysis**. The ideas soon spread to other disciplines in the behavioral science, where unobservable (or *latent*) variables such as 'extroversion', 'political leanings', or 'degree of industrialization' were considered to be reasonable constructs for explanations of inter-variable dependencies.

The stumbling block in the early years was the lack of reliable computational methods for estimating the various model parameters and quantities. Indeed, the first half of the twentieth century was riven with conflicting suggestions and controversies, and many of the proposed methods often failed to find satisfactory solutions. The development of the maximum likelihood approach by Lawley and **Maxwell** in the 1940s was one major advance, but computational problems still remained and were not satisfactorily

resolved till the work of Jöreskog [19]. Now, it is a popular and much used technique throughout the behavioral sciences (although many technical pitfalls still remain, and successful applications require both skill and care). However, it is essentially only applicable to quantitative data. Development with qualitative or categorical variables was much slower, the first account being that by Lazarsfeld and Henry [20] under the banner of *latent structure analysis*. This area then underwent rapid development, and, now, there exist many variants such as *latent class analysis*, *latent trait analysis*, *latent profile analysis*, and others (see **Finite Mixture Distributions**). Further details of these techniques may be found in [4, 9].

Current Trends and Developments

The dramatic developments in computer power over the past twenty years or so have already been noted above, and it is these developments that drive much of the current progress in multivariate analysis. If the first half of the twentieth century can be described as years of mathematical foundations and development, and the succeeding twenty or thirty years as ones of widening practical applicability, then recent developments have centered firmly on computational power. Many of these developments have been brought on by the enormous data sets that arise in modern scientific research, due in no small measure to highly sophisticated and rapid data-collecting instruments. Thus, we have spectroscopy in chemistry, flow cytometry in medicine, and microarray experiments in biology (see **Microarrays**) which all yield multivariate data sets comprising many thousands of observations. Such data matrices bring their own problems and objectives, and this has led to many advances in computationally intensive multivariate analysis. Some specific techniques include: curve fitting through localized nonparametric smoothing and recursive partitioning, a flexible version of which is MARS ('multivariate adaptive regression splines') [12]; the use of wavelets for function estimation [1]; the analysis of data that themselves come in the form of functions [23]; the detection of pattern in two-way arrays by using biclustering [21]; and the decomposition of multivariate spatial and temporal data into meaningful components [3].

While much of the impetus for these developments has come from the scientific area, many of the

resultant techniques are, of course, applicable to the large data sets that are becoming more prevalent in behavioral science also. Indeed, a completely new field of study, **data mining**, has sprung up in recent years to deal with explorative aspects of large-scale multivariate data, drawing on elements of computer science as well as statistics. It is evident that the field is a rich one, and many more developments are likely in the future.

Multivariate Analysis of Variance

The multivariate linear model is used to explain and to analyze the relationship between one or more independent or explanatory variables and $p > 1$ quantitative dependent or response variables that have been observed for each of n subjects. When all the explanatory variables are quantitative, the multivariate linear model is referred to as a *multivariate multiple linear regression model* (see **Multivariate Multiple Regression**). When all the explanatory variables are measured on a qualitative scale, or in other words, when the observations can only be made within a fixed number of factor level combinations, the model is called a *multivariate analysis of variance model*. The techniques used to draw inferences about the model parameters are typically referred to by the generic term multivariate analysis of variance or for short MANOVA.

The simplest MANOVA model is the one-way model in which the p quantitative variables are only affected by a single factor with r levels. The one-way MANOVA model can also be thought of as explaining p quantitative variables arising from r different populations. Typically, the null hypothesis of interest in such a model is that the mean responses of the groups corresponding to the different levels of the factor (or the r populations) are equal. The alternative hypothesis is that there is at least one pair of levels of the factor with different mean responses.

Consider the hypothetical example from Morrison [2] that has been changed slightly for the current presentation (Table 1). Assume that $s = 8$ rats were randomly allocated to each of $r = 3$ drug treatments (i.e., $n = 24$) and weight losses in grams were observed for each rat at two time points (after 1 week and after 2 weeks).

Let y_{ij1} denote the weight loss of rat j with drug i after 1 week, y_{ij2} the weight loss of the same rat after 2 weeks, and $\mathbf{y}_{ij} = (y_{ij1}, y_{ij2})^T$ the vector of observations for rat j on drug i . Let μ_{i1} and μ_{i2} further denote the means of variables 1 and 2 for group i . Then, the expectation of $\mathbf{y}_{ij}$ is $\boldsymbol{\mu}_i = (\mu_{i1}, \mu_{i2})^T$, and a one-way MANOVA model for this

Table 1 Weight losses in $n = 24$ rats (first week, second week)

(8, 10)	(6, 9)	(10, 5)

example is given by

$$\mathbf{y}_{ij} = \boldsymbol{\mu}_i + \mathbf{e}_{ij}, \quad i = 1, 2, \quad r = 3, \\ j = 1, \dots, s = 8, \quad (1)$$

with $\mathbf{e}_{ij} = (e_{ij1}, e_{ij2})^T$, a vector of errors that arises from a multivariate normal distribution (see **Catalogue of Probability Density Functions**) with mean vector $\mathbf{0}$ and (unknown) **covariance matrix** $\boldsymbol{\Sigma}$. Consequently, the vector of observations is multivariate normally distributed with mean vector $\boldsymbol{\mu}_i$ and covariance matrix $\boldsymbol{\Sigma}$. Note that it is assumed that the covariance matrix $\boldsymbol{\Sigma}$ is identical for all vectors of observations (see **Covariance Matrices: Testing Equality of**). Moreover, it is assumed that the vectors of observations are stochastically independent.

To estimate the mean responses, the least squares principle (see **Least Squares Estimation**) can be employed. The least squares estimate, $\hat{\boldsymbol{\mu}}_i$, of the mean response vector $\boldsymbol{\mu}_i$ corresponds to the vector of least squares estimates from separate univariate **analysis of variance** (ANOVA) models, that is, $\hat{\boldsymbol{\mu}}_i = (\hat{\mu}_{i1}, \hat{\mu}_{i2})^T$, with $\hat{\mu}_{i1} = 1/s \sum_{j=1}^s y_{ij1}$ and $\hat{\mu}_{i2} = 1/s \sum_{j=1}^s y_{ij2}$. In the rat example, the least squares estimates of the mean responses are $\hat{\boldsymbol{\mu}}_1 = (7, 7.25)^T$, $\hat{\boldsymbol{\mu}}_2 = (8, 8.5)^T$, and $\hat{\boldsymbol{\mu}}_3 = (14.75, 10.25)^T$.

Also of interest in a MANOVA model is a formal test of zero group difference. This translates into testing the null hypothesis of equal mean responses at each level of the factor, that is,

$$H_0 : \boldsymbol{\mu}_1 = \boldsymbol{\mu}_2 = \dots = \boldsymbol{\mu}_r. \quad (2)$$

In univariate one-way ANOVA, a test for equality of group means is derived by partitioning the total sum of squares into a component that is due to the factor in question and an error sum of squares

2 Multivariate Analysis of Variance

(see **Analysis of Variance**). This principle can be generalized to the multivariate case to derive a test for the multivariate hypothesis H_0 . The *total sum-of-squares-and-products matrix* is given by

$$SST = \sum_{i=1}^r \sum_{j=1}^s (\mathbf{y}_{ij} - \bar{\mathbf{y}}_{..})(\mathbf{y}_{ij} - \bar{\mathbf{y}}_{..})^T, \quad (3)$$

with $\bar{\mathbf{y}}_{..}$ the vector where each component is the arithmetic mean of all the observations of the corresponding quantitative variable. Note that SST is a symmetric $p \times p$ -dimensional matrix. The total sum-of-squares-and-products matrix SST can be partitioned into the sum-of-squares-and-products matrix according to the factor, say SSA , and the error sum-of-squares-and-products matrix, say SSE . It holds

$$SSA = s \sum_{i=1}^r (\hat{\boldsymbol{\mu}}_i - \bar{\mathbf{y}}_{..})(\hat{\boldsymbol{\mu}}_i - \bar{\mathbf{y}}_{..})^T \quad (4)$$

and

$$SSE = SST - SSA. \quad (5)$$

The $p \times p$ -error sum-of-squares-and-products matrix SSE is used to estimate the unknown covariance matrix $\boldsymbol{\Sigma}$. The estimate is given by SSE divided by the so-called error degrees of freedom $r(s-1)$. Note that the error degrees of freedom in MANOVA are identical to the error degrees of freedom in the univariate analysis of variance.

An equivalent assertion holds for the degrees of freedom that corresponds to the sum-of-squares-and-products matrix of the factor in question, here SSA . The degrees of freedom corresponding to SSA in MANOVA are $(r-1)$, which is the same value as in univariate analysis of variance. The degrees of freedom corresponding to a factor in question are often called *hypothesis degrees of freedom*.

In the rat example, the 2×2 -dimensional matrices SSA and SSE are given as

$$SSA = \begin{pmatrix} 301 & 97.5 \\ 97.5 & 36.333 \end{pmatrix} \text{ and } SSE = \begin{pmatrix} 109.5 & 98.5 \\ 98.5 & 147 \end{pmatrix}. \quad (6)$$

In MANOVA models, there are four statistics for testing H_0 , namely, *Pillai's Trace*, *Wilks' Lambda*, the *Hotelling-Lawley Trace*, and *Roy's Greatest Root*. All four test statistics can be calculated from the

eigenvalues $\xi_1, \xi_2, \dots, \xi_p$ (with $\xi_1 \geq \xi_2 \geq \dots \geq \xi_p$) of the matrix product $\mathbf{M}$ of SSA and SSE^{-1} . Specifically, the test statistics are given by

Pillai's Trace

$$\Lambda_P = \sum_{i=1}^p \frac{\xi_i}{1 + \xi_i},$$

Wilks' Lambda

$$\Lambda_W = \prod_{i=1}^p \frac{1}{1 + \xi_i},$$

Hotelling-Lawley Trace

$$\Lambda_{HL} = \sum_{i=1}^p \xi_i,$$

Roy's Greatest Root

$$\Lambda_R = \xi_1. \quad (7)$$

In the rat example, the eigenvalues of $\mathbf{M} = (SSA)(SSE)^{-1}$ are $\xi_1 = 4.4883$ and $\xi_2 = 0.0498$, so that the values of the four test statistics read as follows

Pillai's Trace

$$\Lambda_P = \sum_{i=1}^2 \frac{\xi_i}{1 + \xi_i} = 0.8652,$$

Wilks' Lambda

$$\Lambda_W = \prod_{i=1}^2 \frac{1}{1 + \xi_i} = 0.1735,$$

Hotelling-Lawley Trace

$$\Lambda_{HL} = \sum_{i=1}^2 \xi_i = 4.5381,$$

Roy's Greatest Root

$$\Lambda_R = \xi_1 = 4.4883. \quad (8)$$

When the number of quantitative variables p is only one – the univariate case – then all four test statistics yield equivalent results since the matrix product $(SSA)(SSE)^{-1}$ reduces to the scalar value SSA/SSE that can be simply transformed to the usual F-statistic in univariate analysis of variance. Also, when the hypothesis degrees of freedom are exactly one, as in a simple comparison of a factor with only

two levels, all four statistics yield equivalent results. For a given number of groups, the critical values of the exact distributions of the four test statistics under H_0 can be found in various textbooks, see [3] or [4]. In software packages, however, the values of the test statistics are transformed into F-values and the distributions of these F-values under H_0 are approximated by F distributions with suitable numerator and denominator degrees of freedom (*see Catalogue of Probability Density Functions*). In case of $p = 2$ variables, the distribution of the transformed Wilks' Lambda is exactly F-distributed. The F-value of Roy's Greatest Root is, in general, an upper bound, so that the reported P value is a lower bound and the test tends to be overly optimistic.

Table 2 shows the results of the four multivariate tests for the rat example. All four tests indicate

that the differences between the three drugs are statistically significant.

The one-way MANOVA model can be extended by including additively further factors. These factors can be nested factors, cross-classified factors, or interaction terms, and they usually reflect further structures in the different populations. As in univariate analysis of variance, the focus would be on determining that there was evidence of any factorial main effects or interactions (*see Analysis of Variance*). On the basis of the eigenvalues of the matrix product of a hypothesis sum-of-squares-and-products matrix according to the factor under consideration and the inverse of the error sum-of-squares-and-products matrix, the four tests described above can be applied for each hypothesis test.

Originally, Morrison [2] used the example to motivate a two-way MANOVA model with interactions.

Table 2 Multivariate tests in the hypothetical one-way MANOVA model

Statistic	Value	F-value	Num DF ^c	Den DF ^d	Approx. P value
Pillai's Trace	0.865	8.006	4	42	<0.0001
Wilks' Lambda	0.174	14.004 ^a	4	40	<0.0001

Drug $\times$ sex	Pillai's Trace	0.227	1.152	4	36	0.348
	Wilks' Lambda	0.774	1.159 ^a	4	34	0.347
	Hotelling–Lawley Trace	0.290	1.159	4	32	0.346
	Roy's Greatest Root	0.284	2.554 ^b	2	18	0.106

^aF-statistic is exact.

^bF-statistic is an upper bound.

^cNumerator degrees of freedom of the F distribution of the transformed statistic.

^dDenominator degrees of freedom of the F distribution of the transformed statistic.

The first four rats in each drug group in Table 1 are male and the remainder female. The design, therefore, allows assessment of the main effect of the three drugs, the main effect of sex, and the interactions between drug and sex. The interactions between drug and sex would mean that the differences between male and female rat responses varied across the drugs. Table 3 shows the results from the original two-way analysis.

Again, weight-loss differences between the drugs are statistically significant, whereas the main effect of factor sex and the interaction between drug and sex are not statistically significant. Since the comparison between male and female rats has exactly one hypothesis degree of freedom, the four multivariate tests yield equivalent results.

The question that may now arise is which test statistic should be used. One criterion for choosing a test statistic is the power of the tests. Another criterion is the robustness of the tests when assumptions of the basic data distributions, here independent multivariate normally distributed vectors of observation with equal covariance matrix, are violated. Hand and Taylor [1] extensively discuss the choice of the test statistic in MANOVA models. Wilks' Lambda is most popular in the literature and the statistic is a generalized likelihood ratio test statistic. Pillai's Trace is recommended in [1] on the basis of simulation results for power and robustness of the multivariate tests.

In standard (*fixed effects*) MANOVA, one is usually interested in analyzing the influence of the given

levels of the factors on the dependent variables, as described above. But sometimes, the levels of a factor are more appropriately considered a random sample from an (infinite) number of levels. This can be accommodated by treating the effects of the levels as *random effects*. In this case, besides the covariance matrix of the error term, further covariance matrices according to the random effects, also called *multivariate variance components*, contribute to the total covariance matrix of the dependent variables (for more details random effects MANOVA see [5]).

Multivariate Genetic Analysis

Bivariate Heritability

The genetic and environmental components of covariation can be separated by a technique which is analogous to **factor analysis** [8]. Just as **structural equation modeling (SEM)** can be used to analyze the components of variance influencing a single variable in the case of univariate analysis, SEM can also be used to analyze the sources and structure of covariation underlying multiple variables [8]. When based on genetically informative relatives such as twins, this methodology allows researchers to estimate the extent to which genetic and environmental influences are shared in common by several traits or are trait specific. Information not only comes from the covariance between the variables but also from the cross-twin cross-trait covariances. More precisely, a larger cross-twin cross-trait correlation between monozygotic twin pairs as compared with dizygotic twin pairs suggests that covariance between the variables is partially due to genetic factors. A typical starting point in bivariate and multivariate analysis is the **Cholesky decomposition**. Other methods include common and independent genetic pathway models, as well as genetic simplex models, which will also be discussed.

Multivariate Genetic Analysis

Cholesky Decomposition

The most commonly used multivariate technique in the Classical Twin design (*see Twin Designs*) is the Cholesky decomposition. As shown in Figure 1, the Cholesky is a method of triangular decomposition where the first variable (y_1) is assumed to be caused by a latent factor (*see Latent Variable*) (η_1) that can explain the variance in the remaining variables ($y_2, \dots, y_n$). The second variable (y_2) is assumed to be caused by a second latent factor (η_2) that can explain variance in the second as well as remaining variables ($y_2, \dots, y_n$). This pattern continues until the final observed variable (y_n) is explained by a latent variable (η_n), which is constrained from explaining the variance in any of the previous observed

variables. A Cholesky decomposition is specified for each latent source of variance A, D, C, or E, and as in the univariate case, ACE, ADE, AE, DE, CE, and E models are fitted to the data (*see ACE Model*).

The expected variance–covariance matrix in the Cholesky decomposition is parameterized in terms of n latent factors (where n is the number of variables). All variables load on the first latent factor, $n - 1$ variables load on the second factor and so on, until the final variable loads on the n th latent factor only. Each source of phenotypic variation (i.e., A, C or D, and E) is parameterized in the same way. Therefore, the full factor Cholesky does not distinguish between common factor and specific factor variance and does not estimate a specific factor effect for any variable except the last.

Although symptoms of fatigue and somatic distress are frequently comorbid with anxiety and depressive disorders, a number of studies [6, 7, 14] have demonstrated that a significant proportion of patients with somatic disorders do not meet the criteria for other psychological disorders. As an example of how the Cholesky decomposition can be used

Figure 1 Multivariate Cholesky triangular decomposition, $y_1, \dots, y_n$ = observed phenotypic variables, η_{1-n} = latent factors

Table 1 Phenotypic factor correlations for the factor analytic dimensions of depression, phobic anxiety, and somatic distress. Male correlations appear below the diagonal (reproduced from [3, p. 455])

	Females ($n = 2219$)		
	1	2	3
1 Depression		0.64	0.52
2 Phobic anxiety	0.63		0.58

Results based on Maximum Likelihood.

$\Delta-2LL = -2 \log\text{-likelihood}$.

^a $p < 0.05$,

^b $p < 0.01$,

^c $p < 0.001$.

to resolve these sorts of questions, we administered self-report measures of anxiety, depression, and somatic distress to a community-based sample of 3469 Australian twin individuals aged 18 to 28 years. As shown in Table 1, the phenotypic correlations between somatic distress, depression, and phobic anxiety, for males and females alike, are all high.

The results for the univariate genetic analyses in Table 2 reveal that an additive genetic (*see Additive Genetic Variance*) and **nonshared environmental effects** model best explains individual differences in depression and phobic anxiety scores, for male and female twins alike. The same could not be said for somatic distress because there is insufficient power to choose between additive genetic or shared environment effects as the source of familial aggregation in somatic distress. This limitation can be overcome using multivariate genetic analysis, which has greater power to detect genetic and environmental effects by making use of all the covariance terms between variables. Moreover, it will allow us to determine whether somatic distress is etiologically distinct from self-report measures of depression and anxiety.

As shown in Table 3, an additive genetic and nonshared environment (AE) model best explained the sources of covariation between the three factors. This is illustrated in Figure 2, where 33% (i.e., $0.32^2/0.43^2 + 0.15^2 + 0.32^2$) of the genetic variance in somatic distress is due to specific gene action unrelated to depression or phobic anxiety. In addition, 74% of the individual environmental influence on somatic distress is unrelated to depression and phobic anxiety. These results support previous findings that somatic symptoms are partly etiologically distinct, both genetically and environmentally from the symptoms of anxiety and depression.

Common and Independent Genetic Pathway Models

Alternate multivariate methods can be used to estimate common factor and specific factor variance (*see Factor Analysis: Exploratory*). For instance, the common pathway model in Figure 3a assumes that the genetic and environmental effects (A, C and E) (*see ACE Model*) contribute to one or more latent

Table 3 Multivariate Cholesky decomposition model-fitting results. Results are based on combined male and female data adjusted for sex differences in the prevalence of depression, phobic anxiety, and somatic distress (reproduced from [4, p. 1056])

Model			$-2LL$	df	$\Delta-2LL$	Δdf	p

^b $p < .01$,

^c $p < .001$.

Figure 2 Path diagram showing standardized path coefficients and 95% confidence intervals for the latent genetic (A_1 to A_3) and environmental (E_1 to E_3) effect (reproduced from [4] p. 1057)

intervening variables (η), which in turn are responsible for the observed patterns of covariance between symptoms ($y_1, \dots, y_n$).

This is in contrast to the independent pathway model in Figure 3b, which predicts that genes and environment have different effects on the covariance between symptoms. Because it can be shown algebraically that the common pathway is nested within the independent pathway model, the two models can

be compared using a likelihood ratio chi-squared statistic (see **Goodness of Fit**).

Parker's 25-item Parental Bonding Instrument (PBI) [13] was designed to measure maternal and paternal parenting along the dimensions of Care and Overprotection [11, 12]. However, factor analysis of the short 14-item version based on 4514 females, aged 18 to 45, has yielded three correlated factors: Autonomy, Coldness, and Overprotection [5].

4 Multivariate Genetic Analysis

Figure 3 Common (a) and independent (b) genetic pathway models. η = common factor, $y_1, \dots, y_n$ = observed phenotypic variables, A_ξ , C_ξ & E_ξ = latent genetic & environmental factors, $A_{\varepsilon 1-n}$, $C_{\varepsilon 1-n}$ & $E_{\varepsilon 1-n}$ = latent genetic & environmental residual factors

Table 4 Best fitting univariate models with standardized proportions of variance attributable to genetic and environmental variance (reproduced from [5, p. 390])

PBI dimensions	A	C	E	$-2LL$	df
Coldness	.61	–	.39	5979.01	3603
Overprotection	.22	.24	.54	7438.84	3602
Autonomy	.33	.17	.51	9216.17	3599

Note: A, C & E = additive genetic, shared/common environment, and nonshared environment variance.

Results based on Maximum Likelihood.

$\Delta -2LL = -2 \log\text{-likelihood}$.

^a $p < .05$,

^b $p < .01$,

^c $p < .001$.

Table 5 Comparison of the common and independent pathway models for the PBI dimensions of Autonomy, Coldness, and Overprotection [5]

Model	χ^2 ^a	df	p	AIC
Independent pathway	9.17	15	.87	–20.83
Common pathway	13.39	19	.82	–24.61

Note: Results based on Weighted Least Squares.

AIC = Akaike Information Criterion.

Univariate analyses of the three dimensions, which are summarized in Table 4, reveal that variation in parental Overprotection and Autonomy can be best explained by additive genetic, shared, and nonshared environmental effects, whereas the best fitting model for Coldness includes additive genetic and non-shared environmental effects. As is shown in Table 5, when compared to an independent pathway model,

a common pathway genetic model provided a more parsimonious fit to the three PBI dimensions. The common pathway model is illustrated in Figure 4.

Genetic Simplex Modeling

When genetically informative longitudinal data are available, a multivariate Cholesky can again be

Figure 4 Common pathway genetic model (saturated) for the PBI dimensions with standardized proportions of variance and 95% confidence intervals (reproduced from 5, p. 391). AUTO = Autonomy, OVERP = Overprotection, COLD = Coldness, Results based on Weighted Least Squares

fitted to determine the extent to which genetic and environmental influences are shared in common by a trait measured at different time points. However, this approach is limited in so far as it does not take full advantage of the time-series nature of the data, that is, that causation is unidirectional through time [1].

One solution is to fit a simplex model, which explicitly takes into account the longitudinal nature of the data. As shown in Figure 5, simplex models are autoregressive, whereby the genetic and environmental latent variables at time i are causally related to the immediately preceding latent variables (η_{i-1}).

Eta (η_i) is a latent variable (i.e., A, C, E, or D) at time i , β_i is the regression of the latent factor on

the immediately preceding latent factor η_{i-1} , and ζ_i is the new input or innovation at time i . When using data from MZ and DZ twin pairs, structural equations can be specified for additive genetic sources of variation (A), common environmental (C), nonadditive genetic sources of variation such as dominance or epistasis (D), and unique environmental sources of variation (E).

Because measurement error does not influence observed variables at subsequent time points, simplex designs therefore permit discrimination between transient factors effecting measurement at one time point only, and factors that are continuously present or exert a long-term influence throughout the time series [1, 9]. Although denoted as error variance, the error parameters will also include variance attributable to short-term nonshared environmental effects.

We have used this model-fitting approach to investigate the stability and magnitude of genetic and environmental effects underlying major dimensions of adolescent personality across time [2]. The junior eyesenck personality questionnaire (JEPQ) was administered to over 540 twin pairs at ages 12, 14, and 16 years. Results for JEPQ Neuroticism are presented here.

The additive genetic factor correlations based on a Cholesky decomposition are shown in Table 6. These reveal that the latent additive genetic factors are

Figure 5 General simplex model. β = regression of the latent factor on the previous latent factor ζ = new input or innovation at time i η = latent variable at time i

ζ_{a3} = Genetic innovation at time 3.

Best fitting models in bold.

Figure 6 Best fitting genetic simplex model for female and male Neuroticism (reproduced from [2]). N_{12-16} = Neuroticism 12 to 16 yrs, A_{1-3} , E_{1-3} = additive genetic & nonshared environmental effects, ζ_{a1-3} , ζ_{e1-3} = additive genetic innovations & nonshared environmental innovations, ε_{1-3} = error parameters 12 to 16 yrs double/single headed arrows = variance components/path coefficients

highly correlated. This is consistent with a pleiotropic model of gene action, whereby the same genes explain variation across different time points. As shown in Table 7, the fit of the ACE simplex models provided a better explanation of the Neuroticism time-series data, in so far as the fit was no worse than the corresponding Cholesky decompositions. The final best-fitting AE simplex models for male and female Neuroticism are shown in Figure 6.

It is difficult to imagine that genetic variation in personality is completely determined by age 12. As shown in Figure 6, smaller genetic innovations are observed for male Neuroticism at 14 and 16, as well as female Neuroticism at 14. These smaller genetic innovations potentially hint at age-specific genetic effects related to developmental or hormonal changes during puberty and psychosexual development.

When data are limited to three time points, a common genetic factor model will also provide a comparable fit when compared to the genetic simplex model. Other possible modeling strategies include biometric growth models (see [10]). Despite these limitations, time-series data even when based on three time points still provides an opportunity to test explicit hypotheses of genetic continuity. Moreover, the same data are ideal for fitting univariate and multivariate linkage models to detect quantitative trait loci of significant effect.

The above sections have provided an introduction to bivariate and multivariate analyses and how these methods can be used to estimate the genetic and environmental covariance between phenotypic measures. This should give the reader an appreciation for the flexibility of SEM approaches to address more complicated questions beyond univariate decompositions. For a more detailed treatment of this subject, see [9].

Multivariate Multiple Regression

The multivariate linear model is used to explain and to analyze the relationship between one or more explanatory variables and $p > 1$ quantitative dependent or response variables that have been observed at n subjects. In case all the explanatory variables are qualitative, the multivariate linear model is called the **Multivariate Analysis of Variance (MANOVA) model**. When all the explanatory variables are quantitative, that is a multivariate system of quantitative variables is given in which the relationships between p dependent quantitative variables and, say q , independent quantitative are of interest, then the model is referred to as a *multivariate regression model*. Multivariate regression analysis is used to investigate the relationships when the p dependent variables are correlated. In contrast, when the dependent variables are uncorrelated, relationships can be assessed by carrying out p univariate regression analyses (*see Regression Models*). Often, there is an implied predictive aim in the investigation, and the formulation of appropriate and parsimonious relationships among the variables is a necessary prerequisite.

Consider the small example given in [2]. The data in Table 1 show the four measurements: chest circumference (CC), midupper arm circumference (MUAC), height and age (in months) for a sample on nine girls. One practical objective would be to develop a predictive model for CC and MUAC from knowledge of height and age.

The dependent variables CC and MUAC are highly correlated with each other and Pearson's correlation coefficient is 0.77, so they should be incorporated in a single multivariate regression model for maximum efficiency as multiple regression analyses for each variable separately will ignore this correlation in the construction of hypothesis tests or confidence intervals.

Let y_{i1} denote the CC of the i th girl, y_{i2} the MUAC, x_{i1} the height, and x_{i2} the age; then, the univariate regression models for each variable are

$$y_{i1} = \beta_{01} + \beta_{11}x_{i1} + \beta_{21}x_{i2} + e_{i1},$$

$$i = 1, \dots, n = 9, \quad (1)$$

and

$$y_{i2} = \beta_{02} + \beta_{12}x_{i1} + \beta_{22}x_{i2} + e_{i2},$$

$$i = 1, \dots, n = 9. \quad (2)$$

In the multivariate case, the observations y_{i1} and y_{i2} are put in a row vector so that the model has the form

$$(y_{i1} \ y_{i2}) = (1 \ x_{i1} \ x_{i2}) \begin{pmatrix} \beta_{01} & \beta_{02} \\ \beta_{11} & \beta_{12} \\ \beta_{21} & \beta_{22} \end{pmatrix} + (e_{i1} \ e_{i2}), \quad i = 1, \dots, n = 9. \quad (3)$$

In general, the model for the observed data can be written in matrix form as

$$\mathbf{Y} = \mathbf{X}\mathbf{B} + \mathbf{E} \quad (4)$$

where $\mathbf{Y}$ is the $n \times p$ matrix whose i th row contains the values of the dependent variables for the i th subject, $\mathbf{X}$ is the $n \times (q + 1)$ -matrix, also called the

Table 1 Four measurements taken on each of nine young girls

	Chest circumference (cm)	Midupper arm circumference (cm)	Height (cm)	Age (months)
Individual	y_1	y_2	x_1	x_2

2 Multivariate Multiple Regression

regression matrix, whose i th row contains a one and the values of the explanatory variables for the i th subject, $\mathbf{B}$ is the $(q + 1) \times p$ -matrix of unknown regression parameters, and $\mathbf{E}$ is an $n \times p$ -matrix of random variables whose rows are independent observations from a multivariate normal distribution with mean zero and **covariance matrix** $\mathbf{\Sigma}$. Note that it is assumed that the covariance matrix is identical for each row of $\mathbf{E}$. The assumption of multivariate normality is only necessary when tests or confidence regions have to be constructed for the parameters or the predicted values. For other aspects, it is sufficient to assume that the rows of $\mathbf{E}$ are uncorrelated and have mean zero and covariance matrix $\mathbf{\Sigma}$.

The first step in multivariate regression analysis is to fit a model to the observed data. This requires the estimation of the unknown parameters in $\mathbf{B}$ and $\mathbf{\Sigma}$, which can be done by **maximum likelihood** when normality is assumed or by the least-squares approach (*see Least Squares Estimation*) when no distributional assumptions are made. For the parameter matrix $\mathbf{B}$, both approaches lead to the same estimate so that the actual assumptions are not critical to the outcome of the analysis. For standard application of the theory, it is necessary that the number of subjects n is greater than $p + q$, the total number of quantitative variables. Furthermore, the matrix $\mathbf{X}$ has to be of full rank $(q + 1)$ so that the inverse $(\mathbf{X}^T \mathbf{X})^{-1}$ exists. When these conditions are met, the estimator $\hat{\mathbf{B}}$ of the parameter matrix $\mathbf{B}$ is given by

$$\hat{\mathbf{B}} = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{Y}. \quad (5)$$

Note that the regression matrix $\mathbf{X}$ is identical in all the corresponding univariate regressions analyses. Consequently, the columns of the estimated parameter matrix $\hat{\mathbf{B}}$ are the estimators that would be obtained from the corresponding univariate regression analyses.

The estimator of the covariance matrix $\mathbf{\Sigma}$ is built from the matrix of the residuals

$$\hat{\mathbf{E}} = \mathbf{Y} - \hat{\mathbf{Y}} = \mathbf{Y} - \mathbf{X}\hat{\mathbf{B}}. \quad (6)$$

The maximum likelihood estimator of $\mathbf{\Sigma}$ is given as $\hat{\mathbf{\Sigma}}_{\text{ML}} = \hat{\mathbf{E}}^T \hat{\mathbf{E}}/n$, while an unbiased estimator of $\mathbf{\Sigma}$ is $\hat{\mathbf{\Sigma}}_{\text{unbiased}} = \hat{\mathbf{E}}^T \hat{\mathbf{E}}/(n - q - 1)$. Details of the maximum likelihood derivation can be found in [3] while [4] covers the least-squares approach.

In the example, the estimated parameter matrix is given by

$$\hat{\mathbf{B}} = \begin{pmatrix} 36.7774 & -5.5258 \\ 0.2042 & 0.1405 \\ 0.2545 & 0.3477 \end{pmatrix}. \quad (7)$$

The residual sum-of-squares-and-products matrix is given by

$$\hat{\mathbf{E}}^T \hat{\mathbf{E}} = \begin{pmatrix} 2.4049 & -0.3558 \\ -0.3558 & 2.8713 \end{pmatrix}, \quad (8)$$

so that the maximum likelihood estimate of $\mathbf{\Sigma}$ has the form

$$\hat{\mathbf{\Sigma}}_{\text{ML}} = \frac{1}{9} \hat{\mathbf{E}}^T \hat{\mathbf{E}} = \begin{pmatrix} 0.2672 & -0.0395 \\ -0.0395 & 0.3190 \end{pmatrix}, \quad (9)$$

while the unbiased estimator of $\mathbf{\Sigma}$ is

$$\hat{\mathbf{\Sigma}}_{\text{unbiased}} = \frac{1}{6} \hat{\mathbf{E}}^T \hat{\mathbf{E}} = \begin{pmatrix} 0.4008 & -0.0593 \\ -0.0593 & 0.4786 \end{pmatrix}. \quad (10)$$

When the above assumptions of the general multivariate regression model are fulfilled, inference about the model parameters is possible. In analogy to univariate regression, the first test of interest is of the significance of the regression: do the explanatory variables help at all in predicting the dependent variables, or would simple prediction from the unconditional mean of $\mathbf{Y}$ be just as accurate? Formally, the null hypothesis can be formulated that all the parameters of $\mathbf{B}$ that multiply any of the explanatory variables are zero. Under this null hypothesis, the mean of $\mathbf{Y}$ is $\mathbf{1}\boldsymbol{\mu}^T$ where $\boldsymbol{\mu}$ is the population mean vector of the dependent variables and $\mathbf{1}$ is an n -vector of ones. The maximum likelihood estimator of $\boldsymbol{\mu}$ is $\bar{\mathbf{y}}$, the sample mean vector of the dependent variables. Then, the maximum likelihood estimate of $\mathbf{\Sigma}$ under the null hypothesis can be written as $n\hat{\mathbf{\Sigma}} = \mathbf{Y}^T \mathbf{Y} - n\bar{\mathbf{y}} \bar{\mathbf{y}}^T$. This *total sum-of-squares-and-products matrix* can be decomposed as

$$(\mathbf{Y}^T \mathbf{Y} - n\bar{\mathbf{y}} \bar{\mathbf{y}}^T) = (\hat{\mathbf{Y}}^T \hat{\mathbf{Y}} - n\bar{\mathbf{y}} \bar{\mathbf{y}}^T) + \hat{\mathbf{E}}^T \hat{\mathbf{E}}. \quad (11)$$

Writing $\mathbf{H} = \hat{\mathbf{Y}}^T \hat{\mathbf{Y}} - n\bar{\mathbf{y}} \bar{\mathbf{y}}^T$, the decomposition of the total sum-of-squares-and-products matrix can be summarized in a table just like in MANOVA models (see Table 2).

The null hypothesis of no relationship between the explanatory and the dependent variables can be tested by any of the four multivariate test statistics,

Table 2 MANOVA table for multivariate regression

MANOVA Source	Sum-of-squares-and-products matrix	Degrees of freedom
Multivariate regression	$\mathbf{H}$	q
Residual	$\hat{\mathbf{E}}^T \hat{\mathbf{E}}$	$n - q - 1$
Total	$\mathbf{Y}^T \mathbf{Y} - n \bar{\mathbf{y}} \bar{\mathbf{y}}^T$	$n - 1$

namely, *Pillai's Trace*, *Wilks' Lambda*, the *Hotelling-Lawley Trace*, and *Roy's Greatest Root*. All the test statistics are based on the eigenvalues of the matrix product $(\hat{\mathbf{E}}^T \hat{\mathbf{E}})^{-1} \mathbf{H}$. (For more details see **Multivariate Analysis of Variance**).

Having established that a relationship does exist between the dependent variables and the explanatory variables for predictive purposes, the next objective often is to derive the most parsimonious relationship, that is, the one that has good predictive accuracy while involving the fewest number of explanatory variables. In this context, the null hypothesis to test is that a specified subset of explanatory variables provides no additional predictive information when the remaining explanatory variables are included in the model. Suppose that the null hypothesis is that the last q_2 explanatory variables have no predictive information when the first q_1 explanatory variables are included in the model, $q_1 + q_2 = q$. Then, the sum-of-squares-and-products matrix $\mathbf{H}$ can be partitioned in $\mathbf{H} = \mathbf{H}_{(q_1)} + \mathbf{H}_{(q_2|q_1)}$. The matrix $\mathbf{H}_{(q_1)}$ is given by $\mathbf{H}_{(q_1)} = \mathbf{T} - \tilde{\mathbf{E}}^T \tilde{\mathbf{E}}$, where $\tilde{\mathbf{E}}$ is the residual matrix when only the first q_1 explanatory variables are included in the multivariate regression,

$\mathbf{T}$ is the total sum-of-squares-and-product matrix, and $\mathbf{H}_{(q_2|q_1)} = \mathbf{H} - \mathbf{H}_{(q_1)}$. The tests statistics are then based on the eigenvalues of the matrix product $(\hat{\mathbf{E}}^T \hat{\mathbf{E}})^{-1} \mathbf{H}_{(q_2|q_1)}$.

In statistical software packages, usually the test of the null hypothesis that a specified explanatory variable has no predictive information when all the other explanatory variables are included in the multivariate regression model is reported by default. Since the hypothesis degrees of freedom are exactly one in this situation, the four multivariate tests yield equivalent results (for details see **Multivariate Analysis of Variance**).

Applying the multivariate tests to the example, the results put together in Table 3 are obtained. The analysis indicates that both explanatory variables height and age significantly affect the two dependent variables after adjusting for the effect of the other variable.

The fit of a model to a set of data involves a number of assumptions. These assumptions can relate either to the systematic part of the model, that is, to the form of the relationship between explanatory and dependent variables, or to the random part of the model, that is, to the distribution of the dependent variables. In a multivariate regression model, the matrix of residuals $\hat{\mathbf{E}}$ contains information that can be used to assess the adequacy of the model. If the model is correct and all distributional assumptions are valid, then the rows of $\hat{\mathbf{E}}$ will look approximately like independent observations from a multivariate normal distribution with mean $\mathbf{0}$ and covariance matrix Σ . A detailed discussion of procedures for checking model adequacy is provided in [1] and [2].

Table 3 Multivariate tests on the predictive information of height and age in the example

Variable	Statistic	Value	F Value	Num DF ^b	Den DF ^c	Approx. <i>P</i> value
Height	Pillai's Trace	0.839	12.981 ^a	2	5	0.0105
	Wilks' Lambda	0.161	12.981 ^a	2	5	0.0105
	Hotelling-Lawley Trace	5.193	12.981 ^a	2	5	0.0105
	Roy's Greatest Root	5.193	12.981 ^a	2	5	0.0105
Age	Pillai's Trace	0.785	9.148 ^a	2	5	0.0213
	Wilks' Lambda	0.215	9.148 ^a	2	5	0.0213
	Hotelling-Lawley Trace	3.659	9.148 ^a	2	5	0.0213
	Roy's Greatest Root	3.659	9.148 ^a	2	5	0.0213

^aF statistic is exact.

^bNumerator degrees of freedom of the F distribution of the transformed statistic.

^cDenominator degrees of freedom of the F distribution of the transformed statistic.

Multivariate Normality Tests

Behavioral science researchers frequently gather multiple measures in their research endeavors. That is, for many areas of investigation in order to capture the phenomenon under investigation numerous measures are gathered. For example, Harasym et al. [6] obtained scores on multiple personal traits using the Myers-Briggs inventory for nursing students with three different styles of learning. Knapp and Miller [11] discuss the measurement of multiple dimensions of healthcare quality as part of a system-wide evaluation program. Indeed, as Tabachnick and Fidell [29, p. 3] note, ‘Experimental research designs with multiple DVs (dependent variables) were unusual at one time. Now, however, with attempts to make experimental designs more realistic, . . . , experiments often have several DVs. It is dangerous to run an experiment with only one DV and risk missing the impact of the IV (independent variable) because the most sensitive DV is not measured’.

The assumption of multivariate normality (*see Catalogue of Probability Density Functions*) underlies many multivariate techniques, for example, **multivariate analysis of variance**, **discriminant analysis**, **canonical correlation** and maximum likelihood factor analysis (*see Factor Analysis: Exploratory*), to name but a few. That is to say, many areas of **multivariate analysis** involve parameter estimation and tests of significance and the validity of these procedures require that the data follow a multivariate normal distribution. As Timm [30, p. 118] notes, ‘The study of robust estimation for location and dispersion of model parameters, the identification of **outliers**, the analysis of multivariate residuals, and the assessment of the effects of model assumptions on tests of significance and power are as important in multivariate analysis as they are in univariate analysis.’ In the remainder of this paper, I review methods for assessing the validity of the multivariate normality assumption.

Multivariate Normality

Multivariate normality is most easily described by generalizing univariate normality. In particular, the

normal density function for a random variable y , having mean μ and variance σ^2 is

$$f(y) = \frac{1}{\sqrt{2\pi}\sqrt{\sigma^2}} e^{-(y-\mu)^2/2\sigma^2}. \quad (1)$$

Notationally, when y has the density given in (1) we can write $y \sim N(\mu, \sigma^2)$. As is well known, the density function is depicted by a bell-shaped curve. Now if $\mathbf{y}$ has a multivariate normal distribution with mean μ and covariance Σ , its density is given as

$$g(\mathbf{y}) = \frac{1}{\sqrt{(2\pi)^p} \sqrt{|\Sigma|}} e^{-(\mathbf{y}-\mu)' \Sigma^{-1} (\mathbf{y}-\mu)/2}, \quad (2)$$

where p is the number of variables, $'$ is the transpose operator and $^{-1}$ is the inverse function. Again, notationally, we can say that when $\mathbf{y}$ has the density given in (2) that $\mathbf{y}$ is $\sim N_p(\mu, \Sigma)$. Note that the $p \times p$ population covariance matrix, Σ , is the generalization of σ^2 and the $p \times 1$ mean vector μ is the generalization of μ . The graph of a particular case of (2) is a $(p+1)$ -dimensional bell-shaped surface.

Another correspondence between multivariate and univariate normality is important to note. In the univariate case, the expression $(y - \mu)^2/\sigma^2 = (y - \mu)(\sigma^2)^{-1}(y - \mu)$ in the exponent of (1) is a distance statistic, that is, it measures the squared distance from y to μ in σ^2 units. Similarly, $(\mathbf{y} - \mu)' \Sigma^{-1} (\mathbf{y} - \mu)$ in the exponent of (2) is the squared generalized distance from $\mathbf{y}$ to μ . This squared distance is also referred to as **Mahalanobis's distance statistic**, and a sample estimate (D^2) can be obtained from

$$D^2 = (\mathbf{y} - \bar{\mathbf{y}})' S^{-1} (\mathbf{y} - \bar{\mathbf{y}}), \quad (3)$$

where $\bar{\mathbf{y}}$ is the $p \times 1$ vector of sample means and S is the $p \times p$ Sample covariance matrix (see [8], p. 55).

Properties of Multivariate Normal Distributions

The multivariate normal distribution has a number of important properties that bare on how one can assess whether data are indeed multivariate normally distributed.

- Linear combinations of the variables in $\mathbf{y}$ are themselves normally distributed.
- All marginal distributions for any subset of $\mathbf{y}$ are normally distributed. This fact means that

2 Multivariate Normality Tests

each variable in the set is normally distributed. That is, multivariate normality implies univariate normality for each individual variable in the set $\mathbf{y}$. However, the converse is not true; univariate normality of the individual variables does not imply multivariate normality.

- All conditional distributions (say $\mathbf{y}_1|\mathbf{y}_2$) are normally distributed.

Assessing Multivariate Normality

According to Timm [30, Section 3.7, p. 118], ‘The two most important problems in multivariate data analysis are the detection of outliers and the evaluation of multivariate normality’. Timm presents a very detailed strategy for detecting outlying values and for assessing multivariate normality. The steps he (as well as others) suggests are:

1. Evaluate each individual variable for univariate normality. A number of procedures can be followed for assessing univariate normality, such as checking the skewness and kurtosis measures for each individual variable (see [4, 13, 17], Chapter 4). As well, one can use a global test such as the Shapiro and Wilk [23] test. Statistical packages usually provide these assessments, for example, SAS’s [20] UNIVARIATE procedure (see **Software for Statistical Analyses**).
2. Use normal **probability plots** (Q-Q plots) for each individual variable, plots that compare each sample distribution to population quantiles of the normal distribution. Rencher [17] indicates that many researchers find this technique to be most satisfactory as a visual check for nonnormality.
3. Transform nonnormal variables. Researchers can use Box and Cox’s [3] power transformation. Timm [30, p. 130] and Timm and Mieczkowski [31, pp. 34–35] provide a SAS program for the Box and Cox power transformation (see **Transformation**).
4. Locate outlying values (see the SAS programs in Timm and Mieczkowski [31, pp. 26–31]. If outlying values are present they must be dealt with (see [30, p. 119]). See the references in [33] where they describe a number of (multivariate) outlier detection procedures.

These four steps are for evaluating normality and outlying values with respect to marginal (univariate)

normality. However, as previously indicated, univariate normality is not a sufficient condition for multivariate normality. As Looney [13, p. 64] notes, ‘Even if UVN (univariate normality) is tenable for each of the variables individually, however, this does not necessarily imply MVN (multivariate normality) since there are non-MVN distributions that have UVN marginals.’ Nonetheless, some authors believe that the results from assessing univariate normality are good indications of whether multivariate normality exists or not. For example, Gnanadesikan [5, p. 168] indicates ‘In practice, except for rare or pathological examples, the presence of joint (multivariate) normality is likely to be detected quite often by methods directed at studying the marginal (univariate) normality of the observations on each variable’. This view was also noted by Johnson and Wichern [10, p. 153] – ‘... for most practical work, one-dimensional and two-dimensional investigations are ordinarily sufficient. Fortunately, pathological data sets that are normal in lower dimensional representation but nonnormal in higher dimensions are not frequently encountered in practice’. These viewpoints suggest that it is sufficient to examine marginal and bivariate normality in order to assess multivariate normality. Procedures, however, are available for directly assessing multivariate normality.

Romeu and Ozturk [18] compared goodness-of-fit tests for multivariate normality and their results indicate that multivariate tests of **skewness** and **kurtosis** proposed by Mardia [14, 16] are most reliable for assessing multivariate normality. The skewness and kurtosis measures are defined respectively, as

$$\beta_{1,p} = E[(\mathbf{y} - \boldsymbol{\mu})' \boldsymbol{\Sigma}^{-1} (\mathbf{y} - \boldsymbol{\mu})]^3 \quad (4)$$

and

$$\beta_{2,p} = E[(\mathbf{y} - \boldsymbol{\mu})' \boldsymbol{\Sigma}^{-1} (\mathbf{y} - \boldsymbol{\mu})]^4. \quad (5)$$

The sample estimators, respectively, are

$$\hat{\beta}_{1,p} = \sum_{i=1}^n \sum_{j=1}^n \frac{[(\mathbf{y}_i - \bar{\mathbf{y}})' \mathbf{S}^{-1} (\mathbf{y}_j - \bar{\mathbf{y}})]^3}{n^2} \quad (6)$$

and

$$\hat{\beta}_{2,p} = \sum_{i=1}^n \frac{[(\mathbf{y}_i - \bar{\mathbf{y}})' \mathbf{S}^{-1} (\mathbf{y}_i - \bar{\mathbf{y}})]^4}{n}. \quad (7)$$

The sampling distributions of $\hat{\beta}_{1,p}$ and $\hat{\beta}_{2,p}$ are given by Timm [30, p. 121]. Mardia [14,

15] provided percentage points of $\hat{\beta}_{1,p}$ and $\hat{\beta}_{2,p}$ for $p = 2, 3$, and 4; other values of p or when $n \geq 50$ can be obtained from approximations provided by Rencher [17, p. 113]. A macro provided by SAS (%MULTINORM – see Timm, [30]) can be used to compute these multivariate tests of skewness and kurtosis (see also [31, pp. 32–34]). The macro %MULTINORM can be downloaded from either the Springer-Verlag website – <http://www.springer-ny.com/detail.tpl?isbn=0387953477> or from Timm’s website – <http://www.pitt.edu/~timm>. As Timm indicates, rejection of either test suggests that the data are not multivariate normally distributed; that is, the data contains either multivariate outliers or are not multivariate normally distributed.

Other tests for multivariate normality have been proposed. Looney [13] discusses a number of tests: Royston’s [19] multivariate extension of the Shapiro–Wilk test, Small’s [24] multivariate extensions of the univariate skewness and kurtosis measures, Srivastava’s [26] measures of multivariate skewness and kurtosis, and Srivastava and Hui’s [27] Shapiro–Wilk’s tests. Commenting on these different tests, Looney [13, p. 69] notes that ‘Since no one test for MVN can be expected to be uniformly most powerful against all non-MVN alternatives, we maintain that the best strategy currently available is to perform a battery of tests and then base the assessment of MVN on the aggregate of results.’

If one rejects the multivariate normality hypothesis there are a number of paths that one may follow. First, researchers can search for **multivariate outliers**. However, detecting multivariate outliers is a much more difficult task than identifying univariate outlying values. Graphical procedures might help here (see [22]). The SAS [21] system offers a comprehensive graphing procedure [SAS/INSIGHT – see the discussion and examples in Timm [30, pp. 124–131]. Another approach that researchers frequently employ to detect multivariate outliers is based on Mahalanobis distance statistic (3). That is, one can plot the ordered D_i^2 values against the expected order statistics (q_i) from a chi-squared distribution [see also Timm and Mieczkowski [31, pp. 22–31]. As Timm points out, if the data are multivariate normal, the plotted pairs (D_i^2, q_i) should fall close to the straight line. Timm also notes that there are formal tests for detecting multivariate outliers (see [2]), suggesting however, that these tests have limited value.

Wilcox [32, Chapter 6], on the other hand, presents some newer, more satisfactory, methods for detecting multivariate outliers.

Methods for dealing with multivariate outlying values are also more complex than in the univariate case. As Timm [30] notes, the Box–Cox power transformation has been generalized to the multivariate case by Andrews et al. [1]; however, determining the appropriate transformation is complicated. As an alternative to seeking an appropriate transformation of the data, Timm suggests that researchers can adopt a data reduction transformation, a la principal components analysis, thereby only using a subset (hopefully which are multivariate normally distributed) of the data. Another strategy is to adopt robust estimators instead of the usual least squares estimates; that is, one can utilize trimmed means and a Winsorized variance-covariance matrix. These robust estimators can as well be used to detect outlying values (see [32, 33]) and/or in a multivariate test statistic (see e.g., [12]).

Grouped Data

For many multivariate investigations, data are categorized by group membership (e.g., one-way multivariate analysis of variance). Accordingly, the procedures previously described would be applied to the data within each treatment group (or cell, from a factorial design). Stevens [28] and Tabachnick and Fidell [29] present strategies for applying the previously enumerated procedures for grouped data. As well, they present data sets, indicating statistical software (SAS [20] and SPSS [25]) that can be used to obtain numerical results. It should be noted that when comparing group means it is more important to examine skewness than kurtosis. As DeCarlo [4, p. 297] notes ‘... a general finding for univariate and multivariate data is that tests of means appear to be affected by skew more than kurtosis’.

Numerical Example

To illustrate the use of the methods previously discussed, a hypothetical data set was created by generating data from a lognormal distribution (having skewness = 6.18 and kurtosis = 110.93). In particular, lognormal data were generated for each of two groups ($N_1 = 40$ and $N_2 = 60$), where there were

4 Multivariate Normality Tests

Figure 1 Scores from a lognormal distribution

Table 1 Univariate and multivariate normality tests

Variable	<i>N</i>	Test	Multivariate skewness & kurtosis	Test statistic value	<i>P</i> value
Group 1					
Y_1	40	Shapiro Wilk	.	0.806	.0000
Y_2	40	Shapiro Wilk	.	0.584	.0000
	40	Mardia skewness	15.2437	114.849	.0000
	40	Mardia kurtosis	26.6297	14.728	.0000
Group 2					
Y_1	60	Shapiro Wilk	.	0.699	.0000
Y_2	60	Shapiro Wilk	.	0.485	.0000
	60	Mardia skewness	22.0340	239.200	.0000
	60	Mardia kurtosis	39.4248	30.427	.0000

two dependent measures (Y_1 and Y_2) per subject (see Figures 1 and 2). As indicated, multivariate normality can be assessed by determining whether each of the dependent measures is normally distributed; if not, then multivariate normality is not satisfied. Researchers, however, can choose to bypass these univariate tests (i.e., Shapiro-Wilk) and merely proceed to examine the multivariate measures of skewness and kurtosis with the tests due to Mardia [14]. For completeness, results from both approaches are presented in Table 1. Within each group, both the univariate and multivariate tests for normality are statistically significant.

Having found that the data are not multivariate normally distributed, researchers have to choose some course of action to deal with this problem. As previously indicated, one can search for a transformation to the data in an attempt to achieve multivariate normality, locate outlying values and deal with them, or adopt some robust form of analysis, that is, a procedure (e.g., test statistic) whose accuracy is not affected by nonnormality. Part of the motivation for presenting a two-group problem was to demonstrate a robust solution for circumventing nonnormality. That is, the motivation for the hypothetical data set was that such data could have

Figure 2 Scores from a lognormal distribution

been gathered in an experiment where a researcher intended to test a hypothesis that the two groups were equivalent on the set of dependent measures. The classical solution to this problem would be to test the hypothesis that the mean performance on each dependent variable is equal across groups, that is, $H_0: \mu_1 = \mu_2$, where $\mu_j = [\mu_{j1} \mu_{j2}]$, and $j = 1, 2$. Hotelling's [7] T^2 is the conventional statistic for testing this multivariate hypothesis; however, it rests on a set of derivational assumptions that are not likely to be satisfied. Specifically, this test assumes that the outcome measurements follow a multivariate normal distribution and exhibit a common covariance structure (covariance homogeneity). One solution for obtaining a robust test of the multivariate null hypothesis is to adopt a heteroscedastic statistic (one that does not assume covariance homogeneity) with robust estimators, estimators intended to be less affected by nonnormality. Trimmed means and Winsorized covariance matrices are robust estimators that

can be used instead of the usual least squares estimators of the group means and covariance matrices (*see Robust Statistics for Multivariate Methods*). Lix and Keselman [12] enumerated a number of robust test statistics for the two-group multivariate problem. For the data presented in Figures 1 and 2, the P value for Hotelling's T^2 statistic is .1454, a nonsignificant result, whereas the P value associated with any one of the robust procedures (e.g., Johanson's [9] test) is .0000, a statistically significant result. Consequently, the biasing effects of nonnormality and/or covariance heterogeneity have been circumvented by adopting a robust procedure, a procedure based on robust estimators and a heteroscedastic test statistic.

Summary

Evaluating multivariate normality is a crucial aspect of multivariate analyses. Though the task is considerably more involved than is the case when there is

but a single measure, researchers would be remiss to ignore the issue. Indeed, most classical multivariate procedures require multivariate normality in order to provide accurate tests of significance and confidence coefficients as well as safeguarding the power to detect multivariate effects.

Researchers should at a minimum assess each of the individual variables for univariate normality. As indicated, data cannot be multivariate normal if the marginal distributions are not univariate normal. Checking for univariate normality is straightforward. Statistical packages (e.g., SAS [20], SPSS [25]) provide measures of skewness and kurtosis as well as formal tests (e.g., Shapiro-Wilk). Perhaps, bivariate normality should be assessed as well. For some authors (e.g., [5]; [10]; [28]) these procedures should suffice to assess the multivariate normality assumption. However, others suggest that researchers go on to formally assessing multivariate normality [13, 17, 30]. (One could bypass tests of univariate normality and proceed directly to an examination of multivariate normality.)

The approach most frequently cited for assessing multivariate normality is the method due to Mardia [14]. Mardia presented measures and tests of multivariate skewness and kurtosis. If the data are found to contain multivariate outlying values and/or are not multivariate normal in form, researchers can adopt a number of ameliorative actions. Data can be transformed (not a straightforward task), outlying values can be detected and removed (see [30, 32, 33]) or researchers can adopt robust estimators with robust test statistics (see [12, 30, 32]). With regard to this last option, some authors would recommend that researchers abandon testing and/or examining the classical parameters (e.g., population least squares means and variance-covariance matrices, classical multivariate measures of effect size and confidence intervals) and examine and/or test robust parameters (e.g., population trimmed means and Winsorized covariance matrices) using robust estimators and thus bypass assessing multivariate normality altogether by exclusively adopting robust procedures (e.g., see [32]).

Multivariate Outliers

The presence of outliers in univariate data is readily detected because they must be extreme observations that can easily be identified numerically or graphically. The outliers are amongst the largest or smallest observations and it is not difficult to identify and examine these and perhaps test them for discordancy in relation to the model proposed for the data (*see* **Outliers; Outlier Detection**). By contrast, outliers in multivariate data present special difficulties, primarily because of lack of a clear definition of the ‘extreme observations’ in such a data set. While the intuitive notion that the extreme observations are those that are ‘furthest from the main body of the data’, this does not help locate them since there are many possible ‘directions’ in which they could be separated. As many authors have commented, univariate outliers ‘stick out at one end or the other but multivariate outliers just stick out somewhere’.

Figure 1 shows a plot of two components, B and I, from a set of data containing measurements of nine trace elements (labelled A, B, . . . , I) measured in a collection of 269 archaic clay vessels. There is clearly one outlier ‘sticking out’ in a direction of forty-five degrees from the main body of the data and there are maybe some suspicious observations sticking out in the opposite direction.

Most proposed techniques for pinpointing any outliers that may then be tested formally for discordancy (or, maybe, just examined for deeper understanding of the data) rely on calculations of sample statistics such as the mean and covariance matrix, which

Figure 1 Outlier revealed on bivariate plot

can be seriously affected by the outliers themselves. With univariate data, inflation of sample variance and change in mean does not camouflage their hiding place; by contrast, distortion of the sample covariance can hide multivariate outliers effectively, especially when there are multiple outliers placed in different directions. This feature makes the use of robust estimates of the mean and covariance matrix a possibility to be considered, though this may or may not be effective. This is discussed further below.

As with all outlier problems in the whole range of contexts of statistical analysis, there are three distinct objectives: *identification*, *testing for discordancy* and *accommodation*. Irrespective of whether the first two have been considered, the third of these can be handled by the routine use of robust methods; specifically, use of robust estimates of mean and covariance (*see* **Robust Statistics for Multivariate Methods**). These methods are widely available in many statistical software packages, for example, R, S-Plus, and SAS and are not specifically discussed here (*see* **Software for Statistical Analyses**). Identification may be followed by a formal test of discordancy or it may be that the identification stage has merely revealed simple mistakes in the data recording or, maybe some unexpected feature of interest in its own right. Identification may proceed in step with formal tests in hunting for multiple outliers where *masking* and *swamping* are ever-present dangers.

Identification

Strategies for identification begin with simple graphical methods as an aid to visual inspection. For an $n \times p$ data matrix $\mathbf{X} = (\mathbf{x}_1, \dots, \mathbf{x}_n)'$ representing a random sample of n p -dimensional observations $\mathbf{x}_i$, $i = 1, \dots, n$, univariate plots of original components (or **boxplots** or listing the ordered values numerically) should reveal any simple extreme potential recording errors. Bivariate (or pseudo three-dimensional (*see* **Three Dimensional (3D) Scatterplots**) plots of original components are only worthwhile for low dimensional data, perhaps for $p \leq 10$ or 15, say (an effective upper limit for easy scanning of matrix plots of all pairwise combinations of components). These may not reveal anything other than simple recording errors in a single component which are not extreme enough to have caused concern on first examination of just that component alone. Further, they will not

2 Multivariate Outliers

reveal outliers that are not simple recording errors but are attributable to more interesting unexpected causes. Figure 1 above shows just such an example where the outlier could be a low value of element B or a high value of element I. They are nevertheless worthwhile, especially since such matrix plots are quick and easy to produce (see **Scatterplot Matrices**). For higher dimensional data sets, it is not easy to focus on all of the bivariate scatterplots individually.

A more sophisticated approach is to use an initial dimensionality reduction method as a preliminary step to reduce the combinations of components that need to be examined. The obvious candidate is **principal component analysis**, based on either the covariance or the correlation matrix (or on both in turn) and examining bivariate scatterplots of successive pairs of principal components. These methods have the key advantage in that they can be used even if $n < p$, that is, more dimensions than data points. Here, the rationale is that the presence of outliers will distort the covariance matrix resulting in ‘biasing’ a principal component by ‘pulling it towards’ the outlier, thus allowing it to be revealed as an extreme observation on a scatterplot including that principal component. Clearly, a gross outlier will be revealed on the high order principal components while a minor one will be revealed on those associated with the smaller **eigenvalues**. It is particularly sensible to examine plots of PCs around the ‘cutoff point’ on a scree plot of the eigenvalues since outliers might increase the apparent effective dimensionality of the data set and so be revealed in this ‘additional’ dimension. These methods can be effective for either low numbers of outliers in relation to the sample size or for ‘clusters’ of outliers that arise from a common cause and so ‘stick out’ in the same direction. For large numbers of heterogeneous outliers, then, a robust version of principal component analysis is a possibility, although this loses the rationale that the outliers distort the PCs towards them by distorting the covariance or correlation matrix.

Returning to the measurements of nine trace elements of the clay vessels, Figure 2 shows a scree plot of cumulative variance explained by successive principal components calculated from the correlation matrix of the nine variables on a subset of 53 of the vessels. This suggests that the inherent dimensionality of the data is around five, with the first five principal components containing 93% of the variation and so it could be that outliers would be revealed on plots

Figure 2 Scree plot of cumulative percentage of variance

of principal components around that value. Figure 3 below shows scatter plots of the data referred to successive pairs of the first five principal components.

Inspection of these suggests that the two observations on the right of the lower right-hand plot (i.e. with high scores on the fifth component) would be worth investigating further, though they are not exceptionally unusual. Closer inspection (with interactive brushing) reveals that one of this pair occurs as the extreme top right observation in the top left plot of PC1 versus PC2 in Figure 3, that is, it has almost the highest scores on both of the first two principal components. Further inspection with brushing reveals that the group of three observations on the top right of PC3 versus PC4 (i.e. those with the three highest scores on the fourth component) have very similar values on all other components and so might be considered a group of outliers from a common source.

A more intensive graphical procedure, which is only viable for reasonably modest data sets (say $n < \sim 50$) with more observations than dimensions ($n > p$) and where only a small number of outliers is envisaged is the use of outlier displaying components (ODCs). These are really just linear discriminant coordinates (sometimes called *canonical variate coordinates*) (see **Discriminant Analysis**). For a single outlier, these ODCs are calculated by dividing the data set into two groups, one consisting of just one observation $\mathbf{x}_j$ and the other of the $(n - 1)$ observations omitting $\mathbf{x}_j$, $j = 1, \dots, n$ (so that there is potentially a separate ODC for each observation). It is easily shown that the univariate likelihood ratio test statistic for discordancy of x_j under a Normal mean slippage model calculated from the values projected

Figure 3 Pairwise plots on first five principal components

onto this ODC is numerically identical to the equivalent statistic (see below), calculated from the original p -dimensional data. Thus, the one-dimensional data projected onto the ODC capture all the numerical information on the discordancy of that observation (though the reference distribution for a formal test of discordancy does depend on the dimensionality p). Picking that with the highest value of the statistic will reveal the most extreme outlier. The generalization to two outliers and beyond depends on whether they arise from a common or two distinct slippages. If the former, then there is just one ODC for each possible pair and, if the latter, then there are two. For three or more, the number of possibilities increases rapidly and so the use is limited as a tool for pure detection of outliers to modest data sets with low contamination rates. However, the procedure can be effective for displaying outliers already identified and for plotting subsidiary data in the same coordinate system. Examination of loadings of original components may give information on the nature of the outliers in the spirit of union-intersection test procedures.

Returning to the data on trace elements in clay-pots, the plot in Figure 4 on the left displays the identified outlier in Figure 1 on the single outlier displaying component (ODC) for that observation as the horizontal axis. This has been calculated using all nine dimensions rather than just two as in Figure 1 and this contains all the information on the deviation of this observation from the rest of the data. The vertical axis has been chosen as the first principal component but other choices might be sensible, for example, a component around the cutoff value of four or five or else on a 'subprincipal component': that vector which maximizes the variance subject to the constraint of being orthogonal with the ODC. Examination of the loadings of the trace elements in the ODC show heavy (negative) weighting on element I with moderate contributions from trace elements F (negative) and E (positive). Trace element B, the horizontal axis in Figure 1, has a very small contribution and, thus, it might be suspected that any recording error is in the measurement of element I. A matrix plot of all components (not shown here) does not

Figure 4 Illustrations of outlier displaying components

reveal this, primarily because this pair of elements is the only one exhibiting any strong correlation. It may be seen that there are several further observations separated from the main body of the data in the direction of the ODC, both with low values (as with the outlier) and with high values. Attention might be directed towards these samples. It should be noted, of course, that the sign of the ODC is arbitrary in the sense that all the coefficients could be multiplied by -1 (thus reflecting the plot about a vertical axis), in the same way that signs of principal components are arbitrary.

The figure on the right of Figure 4 displays the subset of the data discussed in relation to Figure 3. Two groups of outliers have been identified. One is the pair of extreme observation on the fifth principal component and these appear on the right of the plot. The other is the triple of extreme observations on the fourth principal component. These appear in the lower left of the plot. However, two further observations appear separated from the main body in this coordinate system (at the top of the plot) and further examination of these samples might be of interest. Informal examination of the loadings of these two ODCs suggests that the first is dominated by trace elements D and E and the second by E, F and I. Whether this information is of key interest and an aid in further understanding is, of course, a matter for the scientist involved rather than purely a statistical result.

The methods outlined above have the advantage that they display outliers in relation to the original data – they are methods for selecting interesting views of the raw data that highlight the outliers. For data sets with large numbers of observations and

dimensions, this approach may not be viable and various, more systematic approaches have been suggested based on some variant of probability plotting. The starting point is to consider ordered values of a measure of generalized squared distance of each observation from a measure of central location $R_j(\mathbf{x}_j, \mathbf{C}, \mathbf{\Gamma}) = (\mathbf{x}_j - \mathbf{C})' \mathbf{\Gamma}^{-1} (\mathbf{x}_j - \mathbf{C})$, where $\mathbf{C}$ is a measure of location (e.g. the sample mean or a robust estimate of the population mean) and $\mathbf{\Gamma}$ is a measure of scale (e.g., the sample covariance or a robust estimate of the population value). The choice of the sample mean and variance for $\mathbf{C}$ and $\mathbf{\Gamma}$ yields the squared **Mahalanobis distance** of each observation from the mean. It is known that if the $\mathbf{x}_j$ comes from a multivariate Normal distribution (*see Catalogue of Probability Density Functions*), then the distribution of the $R_j(\mathbf{x}_j, \mathbf{C}, \mathbf{\Gamma})$ is well approximated by a gamma distribution (*see Catalogue of Probability Density Functions*) with, dependent upon $\mathbf{\Gamma}$, some shape parameter that needs to be estimated. A plot of the ordered values against expected order statistics would reveal outliers as deviating from the straight line at the upper end. Barnett and Lewis [1] give further details and references. It should be noted that, typically, these methods are only available when $n > p$; in other cases, a (very robust) dimensionality reduction procedure might be considered first.

Further, these methods are primarily of use when the number of outliers is relatively small. In cases where there is a high multiplicity of outliers, the phenomena of *masking* and *swamping* make them less effective. An alternative approach, typified by Hadi [2, 3], is based upon finding a ‘clean’ interior subset of observations and successively adding more observations to the subset. Hadi recommends starting

with the $p + 1$ observations with smallest values of $R_j(\mathbf{x}_j, \mathbf{C}, \mathbf{\Gamma})$, with very robust choices for $\mathbf{C}$ and $\mathbf{\Gamma}$. An alternative might be to start by *peeling* away successive *convex hulls* to leave a small interior subset. Successive observations are added to the subset by choosing that with the smallest value of $R_j(\mathbf{x}_j, \mathbf{C}, \mathbf{\Gamma})$, calculated just from the clean initial subset (with $\mathbf{C}$ and $\mathbf{\Gamma}$ chosen as the sample mean and covariance) and with the ordering updated at each step. Hadi gives stopping criterion based on simulations from multivariate Normal distributions, the remaining observations not included in the clean subset being declared discordant.

Tests for Discordancy

Formal tests of discordancy rely on distributional assumptions; an outlier can only be tested for discordancy in relation to a formal statistical model. Most available formal tests presume multivariate Normality; exceptions are tests for single outliers in bivariate exponential and bivariate Pareto distributions. Barnett and Lewis [1] provide some details and tables of critical values for these two distributions. For multivariate Normal distributions (see **Catalogue of Probability Density Functions**, the likelihood ratio statistic for a test of discordancy of a single outlier arising from a similar distribution with a change in mean (i.e., a mean slippage model) is easily shown to be equivalent to the Mahalanobis distance from the sample mean (i.e., $R_j(\mathbf{x}_j, \mathbf{C}, \mathbf{\Gamma})$, with $\mathbf{C}$ and $\mathbf{\Gamma}$ taken as the sample mean and covariance). In one dimension, this is equivalent to the studentized distance from the sample mean. Barnett & Lewis [1] give tables of 5% and 1% critical values of this statistic for various values of $n \leq 500$ and $p \leq 5$, together with similar tables for critical values of equivalent statistics when the population covariance and also both population mean and covariance are known, as well as the case where an independent external estimate of the covariance is available. Additionally, they provide similar

tables for the appropriate statistic for a pair of outliers and references to further sources.

Implementation

Although the techniques described here are not specifically available as an ‘outlier detection and testing module’ in any standard package, they can be readily implemented using standard modules provided for principal component analysis, linear discriminant analysis and robust calculation of mean and covariance, provided there is also the capability of direct evaluation of algebraic expressions involving products of matrices and so on. Such facilities are certainly available in R, S-PLUS and SAS. For example, to obtain a single outlier ODC plot, a group indicator needs to be created, which labels the single observation as group 1 and the remaining observations as group 2 and then a standard linear discriminant analysis can be performed. Some packages may fail to perform standard linear discriminant analysis if there is only one observation in the group. However, it is easy to calculate the single outlier ODC for observation $\mathbf{x}_j$ directly as $\mathbf{\Gamma}^{-1}\mathbf{x}_j$, where $\mathbf{\Gamma}$ is the sample covariance matrix or a robust version of it. The matrix calculation facilities would probably be needed for implementation of the robust versions of the techniques.

Neural Networks

Introduction

The two types of algorithms to be described can be said to be neuro-mimetic. The human or animal brain is comprised of simple computing engines called neurons, and interconnections called *synapses* which seem to store most of the information in the form of electrical signals. Thus, neural network algorithms usually avail of neurons (also called *units*) that perform relatively simple computing tasks such as summing weighted inputs, and then thresholding the value found, usually in ‘soft’ manner. Soft thresholding is, loosely, approximate thresholding, and is counterposed to hard thresholding. A definition is discussed below. The second point of importance in neural network algorithms is that the interconnections between neurons usually play an important role. Since we are mostly dealing with software implementations of such algorithms, the role of electrical signals is quite simply taken up by a weight – a numeric value – associated with the interconnection.

In regard to the categorization or clustering objectives that these algorithms can cater for, there is an important distinction to be made between, on the one hand, the multilayer perceptron, and on the other hand the Kohonen self-organizing feature map.

The multilayer perceptron (MLP) is an example of a *supervised* method, in that a training set of samples or items of known properties is used. Supervised classification is also known as **discriminant analysis**. The importance of this sort of algorithm is that data from the real world is presented to it (of course, in a very specific form and format), and the algorithm learns from this (i.e., iteratively updates its parameters or essential stored values). So, reminiscent of a human baby learning its first lessons in the real world, a multilayer perceptron can adapt by learning. The industrial and commercial end-objective is to have an adaptable piece of decision-making software on the production line to undertake quality control, or carry out some other decision-based task in some other context.

The Kohonen self-organizing feature map is an example of an *unsupervised* method. **Cluster analysis** methods are also in this family of methods (see **k-means Analysis**). What we have in mind here is that the data, in some measure, sorts itself out or

‘self-organizes’ so that human interpretation becomes easier. The industrial and commercial end-objective here is to have large and potentially vast databases go some way towards facilitating human understanding of their contents.

In dealing with the MLP, the single perceptron is first described – it can be described in simple terms – and subsequently the networking of perceptrons, in a set of interconnected, multiple layers to form the MLP. The self-organizing feature map method is then described. A number of examples are given of both the MLP and Kohonen maps.

A short article on a number of neural network approaches, including those covered here, can be seen in [4]. A more in-depth review, including various themes not covered in this article, can be found in [7]. Taking the regression theme further are the excellent articles by Schumacher et al. [10] and Vach et al. [11].

Multilayer Perceptron

Perceptron Learning

Improvement of classification decision boundaries, or assessment of assignment of new cases, have both been implemented using neural networks since the 1950s. The perceptron algorithm is due to work by Rosenblatt in the late 1950s. The perceptron, a simple computing engine which has been dubbed a ‘linear machine’ for reasons which will become clear below, is best related to supervised classification. The idea of the perceptron has been influential, and generalization in the form of multilayer networks will be looked at later.

Let $\mathbf{x}$ be an input vector of binary values, o an output scalar, and $\mathbf{w}$ a vector of weights (or learning coefficients, initially containing arbitrary values). The perceptron calculates $o = \sum_j w_j x_j$. Let θ be some threshold.

If $o \geq \theta$, when we would have wished $o < \theta$ for the given input, then the given input vector has been incorrectly categorized. We therefore seek to modify the weights and the threshold. Set $\theta \leftarrow \theta + 1$ to make it less likely that wrong categorization will take place again.

If $x_j = 0$, then no change is made to w_j . If $x_j = 1$, then set $w_j \leftarrow w_j - 1$ to lessen the influence of this weight.

2 Neural Networks

If the output was found to be less than the threshold, when it should have been greater for the given input, then the reciprocal updating schedule is implemented.

If a set of weights exist, then the perceptron algorithm will find them. A counter example is the exclusive-or, XOR problem, shown in Table 1.

Here, it can be verified that no way exists to choose values of w_1 and w_2 to allow discrimination between the first and fourth vectors (on the one hand), and the second and third (on the other hand).

Network designs which are more sophisticated than the simple perceptron can be used to solve this problem. The network shown in Figure 1 is a feed-forward three-layer network. This type of network is the most widely used. It has directed links from all nodes at one level to all nodes at the next level. Such a network architecture can be related to a linear algebra formulation, as will be seen below. It has been found to provide a reasonably straightforward architecture

Table 1 The XOR, or exclusive-or problem. Linear separation between the desired output classes, 0 and 1, using just one separating line is impossible

Input vector	Desired output
0, 0	0
0, 1	1
1, 0	1
1, 1	0

Figure 1 The MLP showing a three-layer architecture, on the left, and one arc on the right. The circles represent neurons (or units)

which can also carry out learning or supervised classification tasks quite well. For further discussion of the perceptron, Gallant [2] can be referred to for various interesting extensions and alternatives. Other architectures are clearly possible: directed links between all pairs of nodes in the network, as in the Hopfield model, directed links from later levels back to earlier levels as in recurrent networks, and so on.

In a feedforward multilayer perceptron, learning, weight estimation (Figure 1, right), takes place through use of gradient descent. This is an iterative sequence of updates to the weights along the directed links of the MLP. Based on the discrepancy between obtained output and desired output, some fraction of the overall discrepancy is propagated backwards, layer by layer, in the MLP. This learning algorithm is also known as backpropagation. Its aim is to bring the weights in line with what is desired, which implies that the discrepancy between obtained and desired output will decrease. Often a large number of feed forward, and backpropagation updates, are needed in order to fix the weights in the MLP. There is no guarantee that the weights will be optimal. At best, they are locally suboptimal in weight space.

It is not difficult to see that we can view what has been described in linear algebra terms. Consider the matrix W_1 as defining the weights between all input layer neurons, i , and all hidden layer neurons, j . Next consider the matrix W_2 as defining the weights between all hidden layer neurons, j , and all output layer neurons, k . For simplicity, we consider the case of the three-layer network but results are straightforwardly applicable to a network with more layers. Given an input vector, $\mathbf{x}$, the values at the hidden layer are given by $\mathbf{x}W_1$. The values at the output layer are then $\mathbf{x}W_1W_2$. Note that we can ‘collapse’ our network to one layer by seeking the weights matrix $W = W_1W_2$. If $\mathbf{y}$ is the target vector, then we are seeking a solution of the equation $\mathbf{x}W = \mathbf{y}$. This is linear regression. The backpropagation algorithm described above would not be interesting for such a classical problem. Backpropagation assumes greater relevance when nonlinear transfer functions are used at neurons.

Generalized Delta Rule for Nonlinear Units

Nonlinear transformations are less tractable mathematically but may offer more sensitive modeling of real data. They provide a more faithful modeling

of electronic gates or biological neurons. Now, we will amend the delta rule introduced in the preceding section to take into consideration the case of a nonlinear transfer function at each neuron.

Consider the accumulation of weighted values at any neuron. This is passed through a differentiable and nondecreasing transformation. In the matrix formalism discussed above, this is just a linear stretch or rescaling function.

For a nonlinear alternative, this transfer function is usually taken as a sigmoidal one. If it were a step function, implying that thresholding is carried out at the neuron, this would violate our requirement for a differentiable function. Taking the derivative of the transfer function, in other words, finding its slope (in a particular direction), is part and parcel of the backpropagation or gradient descent optimization commonly used.

A sigmoidal function is an elongated ‘S’ function, which is not allowed to buckle backwards. One possibility is the function $y = (1 + e^{-x})^{-1}$. Another choice is the hyperbolic tangent or tanh function: for $x > 20.0$, $y = +1.0$; for $y < -20.0$, $y = -1.0$; otherwise $y = (e^x - e^{-x}) / (e^x + e^{-x})$. Both of these functions are invertible and continuously differentiable. Both have semilinear zones which allow good (linear) fidelity to input data. Both can make ‘soft’ or fuzzy decisions. Finally, they are similar to the response curve of a biological neuron.

A ‘pattern’ is an input observation vector, for instance, a row of an input data table. The overall training algorithm is as follows: present pattern; feed forward through successive layers; backpropagate, that is, update weights; repeat.

An alternative is to determine the changes in weights as a result of presenting all patterns. This so-called ‘off-line’ updating of weights is computationally more efficient but loses out on the adaptivity of the overall approach.

We have discussed how discrepancy between obtained and desired output is used to drive or direct the learning. The discrepancy is called the *error*, and is usually a squared Euclidean distance, or a mean square error (i.e., mean squared Euclidean distance). Say that we are using binary data only. Such data could correspond to some qualitative or categorical data coding. In regard to outputs obtained, in practice, one must use approximations to hard-limiting values of 0, 1; for example, 0.2, 0.8 can be used. Any output value less than or equal to 0.2 is taken as tantamount

to 0, and any output value greater than or equal to 0.8 is taken as tantamount to 1.

If we are dealing instead with quantitative, real-valued data, then we clearly have a small issue to address: a sigmoidal ‘squashing’ transfer function at the output nodes means that output values will be between 0 and 1. To get around this limitation, we can use sigmoidal transfer functions at all neurons, save the output layer. At the output layer we use a linear transfer function at each neuron.

The MLP architecture using the generalized delta rule can be very slow for the following reasons. The compounding effect of sigmoids at successive levels can lead to a very flat energy surface. Hence movement towards fixed points is not easy. A second reason for slowness when using the generalized delta rule is that weights tend to try together to attain the same value. This is unhelpful – it would be better for weights to prioritize themselves when changing value. An approach known as cascade correlation, due to Scott Fahlman, addresses this by introducing weights one at a time.

The number of hidden layers in an MLP and the number of nodes in each layer can vary for a given problem. In general, more nodes offer greater sensitivity to the problem being solved, but also the risk of overfitting. The network architecture which should be used in any particular problem cannot be specified in advance. A three-layer network with the hidden layer containing, say, less than $2m$ neurons, where m is the number of values in the input pattern, can be suggested.

Other optimization approaches and a range of examples are considered in [4, 7]. Among books, we recommend the following: [1], [3], and [9].

Example: Inferring Price from Other Car Attributes

The source of the data used was the large machine learning datasets archive at the University of California Irvine. The origin of the data was import yearbook and insurance reports. There were 205 instances or records. Each instance had 26 attributes, of which 15 were continuous, 1 integer, and 10 nominal. Missing attribute values were denoted by ‘?’. Table 2 describes the attributes used.

Some explanations on Table 2 follow. ‘Symboling’ refers to the actuarial risk factor symbol associated with the price (+3: risky; –3: safe). Attribute

4 Neural Networks

Table 2 Description of variables in car data set

Attribute	Attribute Range
1. symboling	−3, −2, −1, 0, 1, 2, 3

25. highway-mpg	continuous from 16 to 54
26. price	continuous from 5118 to 45 400

number 2: relative average loss payment per insured vehicle year, normalized for all cars within a particular size classification.

As a sample of the data, the first three records are shown in Table 3. The objective was to predict the

price of a car using all other attributes. The coding and processing carried out by us is summarized as follows.

Records with missing prices were ignored, leaving 201 records. All categorical attribute values were mapped onto 1, 2, Missing attribute values were set to zero. Price attribute (to be predicted) was discretized into 10 classes. All nonmissing attributes were normalized to lie in the interval [0.1, 1.0]. A test set of 28 uniformly sequenced cases was selected; a training set was given by the remaining 173 cases.

A three-layer MLP was used, with 25 inputs and 10 outputs. The number of units (neurons) in the hidden layer was assessed on the training set, and covered 4, 8, 12, . . . , 36, 40 neurons. For comparison, a k -Nearest Neighbors discriminant analysis was also carried out with values of $k = 1, 2, 4$. (K -Nearest Neighbors involves taking a majority decision for assignment, among the class assignments found for the k Nearest neighbors. Like MLP, it is a nonlinear mapping method.)

Best performance was found on the training set using 28 hidden layer neurons.

Results obtained were as follows, – learning on the training set and generalization on the test set.

MLP 25–28–10 network:

Learning: 96.53%

Generalization: 71.43%

k -Nearest Neighbors

$k = 1$: Learning: 97.64%, Generalization: 67.86%

$k = 2$: Learning: 85.54%, Generalization: 71.43%

$k = 4$: Learning: 73.99%, Generalization: 71.43%

Hence, the MLP's generalization ability was better than that of 1-Nearest Neighbor's, but equal to that of 2- and 3-Nearest Neighbor's. Clearly, further analysis (feature selection, data coding) could be useful. An advantage of the MLP is its undemanding requirements for coding the input data.

Table 3 Sample of three records from car data set

3, ?, alfa-romeo, gas, std, two, convertible, rwd, front, 88.60, 168.90, 64.10, 48.80, 2548, dohc, four, 130, mpfi, 3.47, 2.68, 9.00, 111, 5000, 21, 27, 13495
3, ?, alfa-romeo, gas, std, two, convertible, rwd, front, 88.60, 168.90, 64.10, 48.80, 2548, dohc, four, 130, mpfi, 3.47, 2.68, 9.00, 111, 5000, 21, 27, 16500
1, ?, alfa-romeo, gas, std, two, hatchback, rwd, front, 94.50, 171.20, 65.50, 52.40, 2823, ohcv, six, 152, mpfi, 2.68, 3.47, 9.00, 154, 5000, 19, 26, 16500

In the example just considered, we had 201 cars, with measures on 25 attributes. Let us denote this data as matrix X , of dimensions 201×25 . The weights between input layer and hidden layer can be represented by matrix U , of dimensions 25×28 . The weights between hidden layer and output layer can be represented by matrix W , of dimensions 28×10 . Let us take the sigmoid function used as $f(\mathbf{z}) = 1/(1 + e^{-\mathbf{z}})$, acting elementwise on its argument, $\mathbf{z}$. The sigmoid function can be straightforwardly extended for use on a matrix (i.e., set of vectors, $\mathbf{z}$). We will denote the outputs as Y , a 201×10 matrix, giving assignments – close to 0 or close to 1 – for all 201 cars, with respect to 10 price categories. Then, finally, our trained MLP gives us the following nonlinear relationship:

$$Y = f((f(XU))W) \quad (1)$$

The Kohonen Self-organizing Feature Map

A self-organizing map can be considered as a display grid where objects are classified (Figure 2). In such a grid, similar objects are located in the same area. In the example (Figure 2, right), a global classification is shown: the three different shapes are located in three different clusters. Furthermore, the largest objects are located towards the center of the grid, and each cluster is ordered: the largest objects are at one side of a cluster, smaller shapes are at the other side.

This leads to an interesting and effective use of the Kohonen self-organizing feature map for both the presentation of information, and as an interactive user interface. As such, it constitutes an active and responsive output from the Kohonen map algorithm.

A self-organizing map is constructed as follows.

- Each object is described by a vector. In Figure 2, the vector has two components: the first one corresponds to the number of angles, and the other one to the width of the area.
- Initially, a vector is randomly associated with each box (or node) of the grid.
- Each document is located in a box whose descriptive vector is the most similar to the object's vector.
- During an iterative learning process, the components of the nodes describing vectors are

(a)

(b)

Figure 2 Notional view of Kohonen self-organizing feature map. Object locations. (a) before learning. (b) after learning

modified. The learning process produces the classification.

The Kohonen self-organizing feature map (SOFM) with a regular grid output representational or display space, therefore involves determining cluster representative vectors, such that observation vector inputs are parsimoniously summarized (clustering objective); and in addition, the cluster representative vectors are positioned in representational space so that similar vectors are close (low-dimensional projection objective) in the representation space.

The output representation grid is usually a square, regular grid. ‘Closeness’ is usually based on the Euclidean distance. The SOFM algorithm is an iterative update one, not similar to other widely used clustering algorithms (e.g., **k-means clustering**). In representation space, a neighborhood of grid nodes is set at the start. Updates of all cluster centers in a neighborhood are updated at each update iteration. As the algorithm proceeds, the neighborhood is allowed to shrink. The result obtained by the SOFM algorithm is suboptimal, as also is the case usually for clustering algorithms of this sort (again, for example, k-means). A comparative study of SOFM performance can be found in [5]. An evaluation of its use as a visual user interface can be found in [6, 8].

Neuropsychology

Neuropsychology is a scientific and clinical discipline that is concerned with two related issues that are, at least theoretically, methodologically, and statistically, distinct. These are: (a) Understanding brain-behavior relationship, and (b) the development and application of methods (including statistical methods) that allow us to assess behavioral manifestations of various types of brain dysfunction.

To illustrate how these clinical and scientific interests come together practically, let us follow a hypothetical case scenario. Imagine a man, let us call him Mr. Fixit, who, while repairing a loose gutter 30 feet above the ground, falls from his ladder. Let us further imagine that this man is fortunate enough to fall into a pile of dry leaves. The man escapes this accident without fractures or internal injuries, although he does fall unconscious briefly. He regains consciousness within a few minutes, feeling woozy, shaky, and sick in his stomach. His wife takes him to the hospital, where he is diagnosed with a concussion and released, with the instruction to take it easy for a few days until the wooziness and nausea go away. Let us further imagine that this man is an owner of a small business, and that his daily activities require him to organize and keep in mind many details as he receives inquiries from potential customers, questions from his five employees, and quotes from suppliers.

The man returns to work after a few days of rest, looking forward to catching up on paperwork, phone calls, purchases, and business meetings. By the end of the first week, however, he feels frustrated, irritated, exhausted, and no closer to catching up than he was when he first returned to work. By the end of the second week, the situation is no better: In fact, not only is he nowhere close to catching up but he is also falling further behind. After a couple of more weeks, the man's wife convinces him that these difficulties seem to be linked to his fall, and that he should see his doctor.

Upon his wife's urging, Mr. Fixit goes back to the neurologist who first examined him, but his visit is not very satisfying: He is told to give it time, that his 'symptoms' are normal, and that he should not worry about it. To complicate matters further, Mr. Fixit has noticed that his ladder has a manufacturing defect that may have caused his fall, and is now considering legal action. And, so, to bring this story

to the topic of this article, Mr. Fixit ends up in a neuropsychologist's office, asking whether his fall might have permanently damaged his brain in such a way as to cause him the difficulties he has been experiencing.

How would a neuropsychologist go about answering such a question? To avoid an unduly complicated discussion, suffice it to say that the neuropsychologist first needs to have a working knowledge of the topics that are subsumed under the heading of 'brain-behavior relationship'. For example, the neuropsychologist must understand what type of damage *typically* occurs in a person's brain as a result of a fall such as the one suffered by Mr. Fixit, and what behaviors are *typically* affected by such damage. Second, the neuropsychologist must possess 'assessment instruments' that allow him to examine Mr. Fixit and interpret the results. The remainder of this chapter focuses on the statistical methods that allow neuropsychologists to both gather knowledge about brain-behavior relationship and to develop appropriate assessment instruments. We will return to the specifics of Mr. Fixit's case to illustrate methodological and statistical issues pertinent to both experimental and clinical neuropsychology.

Statistical Methods Used for Examination of Brain-behavior Relationship

The first question that a neuropsychologist examining Mr. Fixit needs to answer is whether it is realistic that Mr. Fixit's fall resulted in the symptoms that Mr. Fixit describes. To answer questions of this type, neuropsychologists conduct studies in which they compare test performances of individuals who sustained brain injury to healthy controls. Such studies typically use a simple independent *t* Test, or, if more than two groups are compared, a one-way **Analysis of Variance (ANOVA)**. Past studies utilizing such comparisons have demonstrated that patients who have sustained a mild traumatic brain injury (similar to the one sustained by Mr. Fixit) may exhibit difficulties with memory and attention, or difficulties in organization and planning.

Although simple in their design, comparisons of this kind continue to yield invaluable information about the specific nature of patients' deficits. For example, Keith Cicerone [4] recently examined different types of attention in a group of patients similar

to Mr. Fixit. Independent t Tests showed that, from among seven different measures of attention, only those that required vigilant processing of rapidly presented information were performed more poorly among brain-injured, as compared to healthy, participants. In contrast, brief focusing of attention was no different for the two groups.

However, because different measures have different discriminability, a failure to find differences between groups with respect to a particular variable (such as the ability to briefly focus attention) can be difficult to interpret. In particular, it is not clear whether such a failure truly suggests that patients are unimpaired, or whether it suggests inadequate measurement or inadequate statistical power. One way to address this question is to examine **interaction effects** using factorial ANOVA (*see Factorial Designs*). As an example, Schmitter-Edgecombe et al. [9] compared brain-injured and non-brain-injured participants on several indices of memory. They conducted a mixed factor ANOVA with group (injured vs. noninjured) as a between-subjects factor and different components of memory performance as within-subjects factors. Their results yielded a main effect of group, showing that brain-injured patients were generally worse on memory overall. However, the presence of an interaction between group and memory component also allowed the researchers to state with a reasonable degree of certainty that certain facets of memory processing were *not* impaired among brain-injured patients.

In addition to understanding what kinds of deficits are typical among patients who have sustained a brain injury, it is equally important to understand the time course of symptom development and symptom recovery? In other words, is it realistic that Mr. Fixit's symptoms would not have improved or disappeared by the time he saw the neuropsychologist? And, relatedly, should he be concerned that some symptoms will never disappear? Studies that address these questions generally rely on **Repeated Measures Analysis of Variance**, again using group membership as a between-subjects factor and time since injury (e.g., one week, one month, six months) as a within-subjects factor. This method tells us whether either, or both, groups improved in subsequent testing sessions (a within-subjects effect), as well as whether the two groups differ from one another at all, or on only some testing sessions (a between-subjects effect).

As an example, Bruce and Echemendia [3], in their study of sports-related brain injuries, applied this technique using group membership (brain-injured vs. non-brain-injured athletes) as the between-subjects factor and time since injury (2 hours, 48 hours, 1 week, and 1 month) as the within-subjects factor. They found that, whereas healthy participants' performance improved on second testing (due to practice effects), no such improvement was present for the brain-injured group. Essentially, this means that memory performance declined initially in the brain-injured group during the period of 2 to 48 hours, likely due to acute effects of injury such as brain swelling. The results further showed that brain-injured patients' memory abilities recovered significantly by the time of the one-month follow-up assessment. Thus, Mr. Fixit's physician was correct in encouraging Mr. Fixit to 'give it more time'.

Addressing Confounds. As is the case with much of clinical research, research in neuropsychology typically relies on **quasi-experimental designs**. It is well recognized that such designs are subject to a variety of confounds (*see Confounding Variable*). Because much research in clinical neuropsychology is based on datasets that come from actual patients who were examined initially for clinical purposes rather than research purposes, confounds in neuropsychology are perhaps even more troublesome than in some other clinical areas. Thus, for example, although the studies presented up to this point demonstrate that patients like Mr. Fixit exhibit poorer performances than healthy controls with respect to attention and memory, we cannot be absolutely certain that all of the observed group differences are due to the effects of brain injury. Instead, we might argue that people who fall from ladders or are otherwise 'accident prone' tend to suffer from attentional and memory problems even prior to their injuries. In fact, perhaps these accident-prone individuals have always been somewhat forgetful and inattentive, and perhaps these were the very characteristics that caused them to suffer their injuries in the first place.

Bruce and Echemendia [3], in their study of sports-related brain injury, found just such a scenario. Specifically, the athletes who sustained head injuries had lower premorbid (i.e., preinjury) SAT scores than those in a control group. This scenario poses the following questions: What is responsible for the poor

memory and attentional performances of the brain-injured group? Is it the lower premorbid functioning (reflected in their lower SAT scores), or is it the brain injury?

Addressing this question statistically is not as simple as one might think. On the one hand, some investigators attempt to address this problem by using **the Analysis of Covariance (ANCOVA)**, as did Bruce and Echemendia [3] in their study when they used the SAT scores as a **covariate**. On the other hand, Miller and Chapman [6] argue that the *only* appropriate use of ANCOVA is to account for *random* variation on the covariate, not to ‘control’ for differences between groups. However, while it is true that the results of an ANCOVA regarding premorbid differences are not easy to interpret, some investigators maintain that conducting an ANCOVA in this situation is appropriate, as it might at least afford ruling out the effect of the covariate. In particular, if group differences continue to be present even after a covariate is added to the analysis, it is clear that the dependent variable, not the covariate, accounted for such differences. If, on the other hand, adding a covariate abolishes a given effect, the results cannot be readily interpreted.

To avoid this controversy, some researchers match groups on a variety of potential confound variables, most commonly age, education, and gender. This approach, however, is not controversy-free either, as it may lead to samples that are unrealistically constrained or are not representative of the population of interest. For example, it is well understood that mild traumatic brain injury patients who are involved in litigation (as Mr. Fixit might become, due to his defective ladder) perform more poorly on neuropsychological tests than those who are not involved in litigation [8]. It is also well understood that a substantial subgroup of litigating patients consciously or unconsciously either feign or exaggerate their cognitive difficulties [1]. Thus, researchers who are interested in understanding the nature of cognitive deficits resulting from a traumatic brain injury often remove the litigating patients from their sample. However, it is possible that these patients litigate *because of* continued cognitive difficulties. For example, would Mr. Fixit even think of litigation (regardless of whether he noticed the defect on his ladder) if he were not experiencing difficulties at work? Thus, by excluding these patients from our samples, we may be underestimating the extent of

deleterious effects of traumatic brain injury on cognition. Because of these statistical and methodological controversies, accounting for confounds is a constant struggle both in neuropsychology research and in neuropsychology practice. In fact, these issues will figure largely in the mind of Mr. Fixit’s neuropsychologist who attempts to determine the true nature and severity of Mr. Fixit’s difficulties.

Neuropsychological Assessment Instruments

Understanding the realistic nature and course of Mr. Fixit’s difficulties allows the clinician to select a proper battery of tests for Mr. Fixit’s assessment. However, there are hundreds of neuropsychological instruments available on the market. How does a neuropsychologist choose the most appropriate ones for a given case? Research and statistical methods that address different aspects of this question are described below.

Validity

The first step in selecting assessment instruments is to select instruments that measure the constructs of interest (*see* **Validity Theory and Applications**). In this case, the various functional domains that might have been affected by Mr. Fixit’s fall, such as attention and memory, represent our constructs. While some constructs and the related assessment instruments are relatively straightforward and require relatively little validation past that conducted as part of the initial test development, others are complex or even controversial, requiring continual reexamination. An example of such a complex construct is a functional domain called *executive abilities*. Executive abilities allow people to make intelligent choices, avoid impulsive and disorganized actions, plan ahead, and follow through with plans. Research shows that executive abilities are sometimes compromised following a traumatic brain injury. Given Mr. Fixit’s difficulties managing his small business, it is quite likely that impaired executive functions are to blame. Assessment of executive abilities is arguably among the greatest challenges in clinical neuropsychology, with much research devoted to the validation of measures that assess this domain.

A common statistical method for addressing the question of a test’s construct validity is a factor

analysis (*see* **Factor Analysis: Exploratory**). Factor analysis can demonstrate that the items on a test follow a certain theoretically cogent structure. Typically, a test's factor structure is examined during the initial test development process. However, it is sometimes the case that factor analysis research may offer new insights even after a test has been in clinical use for some time. For example, based on their day-in and day-out experiences with patients, clinicians may sometimes become aware of certain qualitative aspects of test performance that may be related to specific disease processes. For these clinical impressions to be confirmed, a formal validation is required. An example of such a validation study was that of Osmon and Suchy [7] who examined several qualitative aspects of performance on the Wisconsin Card Sorting Test, a popular test of executive functioning. Factor analyses yielded three factors, demonstrating that different types of errors represent separate components of executive processing. Thus, the results support the notion that the Wisconsin Card Sorting Test assesses more than one executive ability, which is in-line with the conceptualization of executive functions as a nonunitary construct.

In addition to examining the factor structure of a test, validation can also be accomplished by examining whether a measure correlates with other instruments that are known to measure the same construct. A study conducted by Bogod and colleagues [2] is an example of this approach. Specifically, these researchers were interested in determining the validity of a measure of self-awareness (called SADI). Self-awareness, or awareness of deficits, is sometimes impaired in patients who have suffered a traumatic brain injury. Bogod and colleagues used such patients to examine whether SADI scores correlated with another index of self-awareness. These analyses yielded the first tentative support for the measure's construct validity. In particular, the analyses showed that, although the SADI did not correlate with the deficits reported by the patient or the patients' relatives, it did correlate with the degree of discrepancy between the patients' and the relatives' reports. In other words, the measure was unrelated to the severity of one's disability, but rather to one's inability to accurately appraise one's disability. Additionally, because deficits in self-awareness are, at least theoretically, related to deficits in executive functioning, Bogod and colleagues examined the relationship

between the SADI and measures of executive functions. Medium size correlations provided additional support for the measure, as well as for the theoretical conceptualization of the construct of self-awareness and its relationship to other cognitive abilities.

However, demonstrating that a particular test measures a particular cognitive construct does not address the question of whether a deficit on a test relates to real-life abilities. In other words, does a test predict how a person will function in everyday life? This is often referred to as the test's 'ecological validity'. As an example, Suchy and colleagues [10] determined whether an executive deficit identified during the course of hospitalization predicted patients' daily functioning following discharge. These researchers used a series of Stepwise Multiple Regressions (*see* **Multiple Linear Regression**) in which different behavioral outcomes (e.g., whether patients prepare their own meals, take care of their hygiene needs, or manage their own finances) served as criterion variables and three factors of the Behavioral Dyscontrol Scale (BDS), a measure of executive functioning, served as predictors. Because Stepwise Multiple Regressions can be used to generate parsimonious models of prediction, the authors showed not only that the BDS was a significant predictor of actual daily functioning, but also which components of the measure were the best predictors. A caution about Stepwise Multiple Regressions is that it can unduly capitalize on the idiosyncrasies of the sample. As a result, only a small difference in sample characteristics can lead to a variable's exclusion or inclusion in the final model. For that reason, it is a good idea to test the stability of generated models by repeating the analyses with random subsamples drawn from the original sample. Discrepancies in results must be resolved both statistically and theoretically prior to drawing final conclusions.

Finally, because patients and settings vary widely across different neuropsychological studies, it is common for a single measure to yield a variety of contradictory findings. For example, the sensitivity and specificity of the Wisconsin Card Sorting Test has been an ongoing source of controversy in neuropsychology research and practice. Some studies have found the measure to have good sensitivity and specificity for frontal lobe integrity (the presumed substrate of executive abilities), whereas others have shown no such relationship. Recently, Demakis [5] addressed the ongoing controversy about the test's

utility by conducting a **meta-analysis**. The composite finding of 24 studies yielded small but statistically significant effect sizes, providing validation for both sides of the argument: Yes, the measure is related to frontal lobe functioning, and, yes, the relationship is weak.

Clinical Utility

Research and statistical methods described up to this point allow us to determine that, on average, patients who have suffered a traumatic brain injury perform more poorly than healthy controls on validated measures of executive functioning, attention, and memory. This means that Mr. Fixit's difficulties might very well be real. However, we don't know which measures are the best for making decisions about Mr. Fixit's specific situation. To answer that question, researchers must examine how successful different measures are at patient classification.

Traditionally, **Discriminant Function Analysis (DFA)** has been the statistic of choice for examining a measure's classification accuracy. Although this procedure provides information about the overall hit rate and its statistical significance, these results do not always generalize to clinical settings. First, this method produces cutting scores that will maximize the overall hit rate, regardless of what the clinical needs are. In other words, in some clinical situations, it may be more useful to have a test with a high specificity, whereas, in other situations, a test of high sensitivity may be needed. Second, classifications are maximized by using discriminant function coefficients that require a conversion of the raw data. Such conversions are not always practical, and, as a result, are generally of little clinical use.

In recent years, the **Receiver Operating Characteristic (ROC) Curve** has gained popularity over DFA in neuropsychology research. This procedure allows determination of exact sensitivity and specificity associated with every possible score on a given test. Based on ROC data, one can choose a cutting score with a high sensitivity to 'rule in' patients who are at risk for a disorder, high specificity to 'rule out' patients who are at low risk for a disorder, or an intermediate sensitivity and specificity to maximize the overall hit rate. Additionally, the ROC analysis allows determination of whether the classification rates afforded by the test are statistically significant.

To conduct an ROC analysis, one needs a sample of subjects for whom an external validation of 'impaired' is available. Depending on the setting in which a test is employed, a variety of criteria can be used. Some examples of external criteria of impairment include inability to succeed at work (as was the case with Mr. Fixit), inability to live independently (a common issue with the elderly), or an external diagnosis of a condition based on neuroradiology or other medical data. By conducting an ROC analysis with such a sample, empirically based cutting scores can be applied in clinical settings to make decisions about patients for whom external criteria of impairment are not known.

Conclusions

A variety of statistical techniques are needed to conduct research that allows a clinician to address even one clinical scenario. In our hypothetical scenario, *t* Tests, ANOVAs, and ANCOVAs helped our clinician to determine whether Mr. Fixit's complaints were realistic and what cognitive difficulties might account for his complaints. Factor analyses, correlational analyses, meta-analyses, DFA, and ROC curve analyses helped determine what measures are most appropriate for assessing the exact nature of Mr. Fixit's difficulties. Multiple regressions allowed predictions about the impact of his deficits on his everyday functioning.

New Item Types and Scoring

Computers have been used to administer tests since the 1960s [2]. At first, computerized tests were just that; tests were still comprised of the traditional multiple-choice questions, but examinees read the items from a computer screen or teletype rather than a printed test booklet. Improvements in the technological capabilities of the computer over the decades have revolutionized the field of testing and assessment. (*see Computer-Adaptive Testing*) Advances in hardware capabilities (e.g., memory, hard disks, video adaptor cards, sound cards) and software (e.g., graphical user interfaces, authoring tools) have enabled test developers to create a variety of new item types. Researchers and test developers have devised these new item types to assess skills and performance abilities not well measured by traditional item types, as well as to measure efficiently characteristics traditionally assessed by a multiple-choice format.

In this entry, a review of many of these new item types is presented. Moreover, issues related to scoring innovative items are described. Because the area is rapidly growing and changing, it is impossible to give an exhaustive review of all developments; however, some of the most important advancements in new item types and related scoring issues are highlighted.

Simulations

Recently, several licensing and credentialing boards have concluded that traditional multiple-choice items may adequately assess candidates' factual knowledge of a given domain, but fail to measure the skills and performance abilities necessary for good job performance. For example, once candidates pass the Uniform Certified Public Accountant Examination (UCPAE), they, as accountants, do not answer multiple-choice questions on the job; instead they must often address vague and ambiguous problems posed to them by clients. As a result, many licensing boards have begun incorporating simulated workplace situations in their exams. These simulations are designed to faithfully reflect important challenges faced by employees on the job; adequate responses are required for satisfactory performance.

In April of 2004, the American Institute of Certified Public Accountants (AICPA) implemented a new computerized UCPAE comprising multiple-choice items and simulations. The simulations require examinees to perform activities that are required to answer questions posed by clients. Consequently, they may enter information into spreadsheets, complete cash flow reports, search the definitive literature (which is available as a on-line resource), and write a letter to the client that provides their advice and states its justification. Clearly, the advantage of this assessment format is that it provides an authentic test of the skills and abilities necessary to be a competent accountant.

One disadvantage of the simulation format is that many of the items are highly interdependent due to the nature of the task. For example, a typical simulation, which might require about 20 responses, might require an examinee to enter several values in a balance sheet. If an examinee's first entry in the balance sheet is incorrect, it is unlikely that his/her entry in the next cell will be correct. Having two highly intercorrelated items (i.e., the interitem correlation may exceed 0.90) is problematic because, essentially, the same question is asked twice. The examinee who correctly answers the first item is rewarded twice, whereas the candidate who answers the first item incorrectly is penalized twice. As a result, the AICPA is considering alternative scoring methods, such as not scoring redundant items or giving examinees one point if they correctly answer all parts of redundant sets of items and zero points if they do not.

In 1999, National Board of Medical Examiners (NBME) changed its licensing test to a computerized format, which included simulated patient encounters [5]. These simulations were developed to assess critical diagnostic skills required to be a competent physician. The candidate assumes the role of the physician and must treat simulated patients with presenting symptoms. On the basis of these symptoms, the candidate can request medical history, order a test, request a consultation, or order a treatment; virtually any action of a practicing physician can be taken. As in the real world, these activities take time. Therefore, if the candidate orders a test that requires an hour to complete, the candidate must advance an on-screen clock by one hour in order to obtain the results. Simultaneously, the patient's symptoms and condition also progress by one hour. Clearly, this simulation format provides a highly authentic test of the

2 New Item Types and Scoring

skills required to be a competent physician; however, scoring becomes very complicated because candidates can take any of literally thousands of actions.

Items that Incorporate Media

Early computerized test development efforts focused on multiple-choice items were presented in a format that included text and simple graphics [7]. However, incorporating media within a test has improved measurement in tests such as Vispoel's [10] tonal memory computer adaptive test (CAT) that assesses musical aptitude, Ackerman, Evans, Park, Tamassia, and Turner's [1]. Test of Dermatological Skin Disorders that assesses the ability to identify and diagnose different types of skin disorders, and Olson-Buchanan, Drasgow, Moberg, Mead, Keenan, and Donovan's [8] Conflict Resolution Skills Assessment that measures the interpersonal skill of conflict resolution.

Vispoel's [10] tonal memory CAT improves on traditional tests of music aptitude that are administered via paper and pencil with a tape recorder controlled by the test administrator at the front of the room. Biases such as seat location and disruptive neighbors are eliminated because each examinee completes the test via computer with a pair of headphones, which offers superior sound quality to that of a tape cassette. Vispoel [10] demonstrated that fewer questions have to be administered because the test is adaptive, which reduced problems of fatigue and boredom; furthermore, the test pace is controlled by the examinee rather than the administrator. Many of the benefits of Vispoel's tonal memory CAT are analogous to the benefits of Ackerman et al.'s Test of Dermatological Skin Disorders [1]. For example, this test, which scores examinees on their ability to identify skin disorders, is improved when computerized because the high-resolution color image on a computer monitor is superior to that of a slide projector. Moreover, the computerized test allows examinees to zoom on an image. Note that examinees seated at the back of the room are no longer at a visual disadvantage, and, the respondent, not the test administrator, controls the pace of item administration.

Olson-Buchanan et al.'s [8] Conflict Resolution Skills Assessment presents video clips of realistic workplace problems a manager might encounter and then asks the examinee what he/she would do in each situation. Its developers believe that examinees become more psychologically involved in the

situation when watching the video clips than when reading passages. Chan and Schmidt [4] found that reading comprehension correlated 0.45 with a paper-and-pencil assessment of an interpersonal skill, but only 0.05 with a video-based version. Thus, it appears that the video format enables a more valid assessment of interpersonal skill by reducing the influence of cognitive ability. On the other hand, scoring these types of items presents a challenge. Is it best to use subject matter experts to determine the scoring or should empirical keying be used? Are the wrong options equally wrong or are some better than others? If so, how do you score them? Test developers are investigating the best way to score these item types.

Innovative Mathematical Item Types

Traditional standardized tests assessing mathematical ability such as the American College Testing (ACT) and the Scholastic Assessment Test (SAT) rely solely on a multiple-choice format and, consequently, examinees have a high probability (25% if there are four options) of answering correctly by simply guessing. However, three novel mathematics item types, *mathematical expressions*, *generating examples*, and *graphical modeling*, require examinees to construct their own response [3], which reduces the probability of answering these problems correctly by guessing to roughly zero.

Mathematical expressions are items that require examinees to construct a numerical equation to represent the problem [3]. For example, if x is the mean of 7, 8, and y , what is the value of y in terms of x ? The obvious solution is $y = 3x - 7 - 8$; however, $y = 3x - 15$, $y = 3x - (7 + 8)$, and $y = (6x - 14 - 16)/2$ are also correct. In fact, there are an infinite number of correct solutions, which makes scoring problematic. Fortunately, Bennett et al. [3] developed a scoring algorithm, which converts answers to their simplest form. In a test of the scoring algorithm, Bennett et al. (2000) found the accuracy to be 99.6%.

Generating examples are items that require examinees to construct examples that fulfill the constraints given in the problem [3]. For example, suppose x and y are positive integers and $2x + 4y = 20$; provide two possible solution sets for x and y (Solution: $x = 4$, $y = 3$ and $x = 6$, $y = 2$). Again, there is more than one right answer, and therefore scoring is not as straightforward as with multiple-choice items.

Graphical modeling items require examinees to construct a graphical representation of the information provided in the problem [3]. For example, examinees may be asked to use a grid to draw a triangle that has an area of 12. As before, there are many solutions to this problem. These problems require the test developer to create and validate more extensive scoring rules than a simple multiple-choice key. Nonetheless, by requiring examinees to construct responses, Bennett et al. [3] showed that these item types have enriched the assessment of mathematical ability.

Innovative Verbal Item Types

Like standardized tests of mathematical ability, most tests of verbal ability rely on multiple-choice items. However, recent innovations in the assessment of verbal ability may change the status quo. The following section describes two examples of innovation in verbal assessment: *passage editing* and *essay with automated scoring*.

A traditional item type used to assess verbal ability requires examinees to read a sentence with a section underlined and choose from a list of options the alternative that best corrects the section grammatically. The problem with this type of item is that it points the examinee to the error by underlining it. Would examinees know there was an error if it was not pointed out for them? Passage editing bypasses this problem because it requires examinees to locate an error within a passage (nothing is underlined) as well as correct it [6, 11]. This results in a more rigorous test of verbal ability than the traditional format because it assesses both the ability to locate errors as well as fix them.

It is difficult to dispute the argument that having an examinee write an essay is the most authentic test of writing ability. Unfortunately, essays are often omitted from standardized tests because they are costly and time-consuming to score. However, innovations in computerized scoring such as *e-rater* [9] make the inclusion of essays a realistic option. *E-rater* is a computerized essay grader that utilizes scoring algorithms based on the rules of natural language processing. In an interesting study examining the validity of *e-rater*, Powers et al. [9] invited a wide variety of people to submit essays that might be scored incorrectly by the computer. A Professor of Computational Linguistics received the highest possible score by

writing a paragraph and then repeating it 37 times. *E-rater* has since been improved, and Powers et al. [9] state that *e-rater* is now capable of correctly scoring most of the essays that had previously tricked it.

Conclusion

Psychological testing and assessment has been revolutionized by the advent of the computer, and, specifically, improvements in the capabilities of modern computers. As a result, test developers have explored a wide variety of innovative approaches to assessment; however, there is a cost. Scoring innovative items types is rarely as straightforward as a multiple-choice key and often quite complex. This review presents some of the newest innovations in item types along with related scoring issues. These innovations in item types and concomitant scoring algorithms represent genuine improvement in psychological testing.

Neyman, Jerzy

Born: April 16, 1894, Bendery, Russia.

Died: August 5, 1981, Berkeley, CA.

Jerzy Neyman spent the first half of his life moving back and forth between Russia, Poland, England, and France but in the last half of his life firmly ensconced in Berkeley, California. In the process, he helped lay the foundation of modern statistical theory and built one of the major statistics departments in the United States.

Jerzy Neyman was born to a Polish family in Russia in 1894. His father was an attorney, and Neyman was educated at home until he was 10, at which point he was fluent in five languages. When his father died, the family moved to Kharkov, where he attended school and eventually university. While at university, he read the work of Lebesgue and proved five theorems on the Lebesgue integral on his own. At the end of the First World War, he was imprisoned briefly. He remained at Kharkov, teaching mathematics until 1921, at which point he moved to Poland. He took a position as a senior statistical assistant at the Agricultural Institute but soon moved to Warsaw to pursue his PhD., which he received in 1924.

In 1925, Neyman won a Polish Government Fellowship to work with **Karl Pearson** in London, but he was disappointed with Pearson's knowledge of mathematical statistics. In the next year, he won a Rockefeller Fellowship to study pure mathematics in Paris.

While in London, Neyman had formed a friendship with Pearson's son **Egon Pearson**, and they began to collaborate in 1927 while Neyman was still in Paris. This collaboration had profound effects on the history and theory of statistics.

In 1928, Neyman returned again to Poland to be head of the Biometric Laboratory at the Nencki Institute of Warsaw. He remained there until returning to London in 1934 but continued his collaboration with Egon Pearson throughout that period.

The Neyman–Pearson approach to hypothesis testing is outlined elsewhere (*see* **Neyman–Pearson Inference**) and will not be elaborated on here. But it is worth pointing out that their work developed the concepts of the *alternative hypothesis*, **power**,

Type II errors, 'critical region', and the 'size' of the critical region, which they named the *significance level*. Neyman had also developed the concept of a '**confidence interval**' while living in Poland, though he did not publish that work until 1937.

In 1934, Neyman returned to London to take a position in Pearson's department, and they continued to publish together for another four years. They clashed harshly with **Fisher**, who was at that time the head of the Eugenics department at University College, which was the other half of Karl Pearson's old department. Those battles are well known to statisticians and were anything but polite – especially on Fisher's side.

In 1938, Neyman accepted a position of Professor of Mathematics at Berkeley and moved to the United States, where he was to remain. He established and directed the Statistics Laboratory at Berkeley, and in 1955 he founded and chaired the Department of Statistics. O'Connor and Robinson [2] note that his efforts at establishing a department were not always appreciated by all at the University. An assistant to the President of Berkeley once wrote:

Here, a willful, persistent and distinguished director has succeeded, step by step over a fifteen-year period, against the wish of his department chairman and dean, in converting a small 'laboratory' or institute into, in terms of numbers of students taught, an enormously expensive unit; and he argues that the unit should be renamed a 'department' because no additional expense will occur.

That quotation will likely sound familiar to those who are members of academic institutions.

In 1949, he published the first report of the Symposium of Mathematical Statistics and Probability, and this symposium became the well-known Berkeley Symposium, which continued every five years until 1971.

Additional material on Neyman's life and influence can be found in [1], [3], and [4].

Neyman–Pearson Inference

Jerzy Neyman [9] credits **Pierre Laplace** [5] with being the first to attempt to test a statistical hypothesis. Prominent among the many people who have contributed to the development of mathematical statistics from the time of Laplace until now are the developers of schools of thought that have dominated the use of statistics by psychologists for the analysis of experimental data. One of these schools of thought derives from the work of **Ronald A. Fisher**, the other from that of Neyman and **Egon Pearson** (son of **Karl Pearson**, for whom the Pearson correlation coefficient was named). A third school, emanating from the work of the **Reverend Thomas Bayes**, has had considerable impact on the theorizing of psychologists, especially in their efforts to develop normative and descriptive models of decision making and choice, but it has been applied much less to the analysis of experimental data, despite eloquent pleas by proponents of **Bayesian analysis** for such an application.

The Collaboration

The collaboration between Neyman and E. Pearson began when the former spent a year as a visitor in Karl Pearson's laboratory at University College, London in 1925. It lasted for the better part of a decade during which time the two co-authored several papers. The collaboration, which has been recounted by Pearson [15] in a Festschrift for Neyman, was carried on primarily by mail with Neyman in Poland and Pearson in England.

In their first paper on hypothesis testing, Neyman and Pearson [10] set the stage for the ideas they were to present this way: 'One of the most common as well as most important problems which arise in the interpretation of statistical results, is that of deciding whether or not a particular sample may be judged as likely to have been randomly drawn from a certain population, whose form may be either completely or only partially specified. We may term Hypothesis A¹ the hypothesis that the population from which the sample $\sum$ has been randomly drawn is that specified, namely Π . In general the method of procedure is to apply certain tests or criteria, the results of which will

enable the investigator to decide with a greater or less degree of confidence whether to accept or reject Hypothesis A, or, as is often the case, will show him that further data are required before a decision can be reached' (p. 175).

In this paper, they work out the implications of certain methods of testing, assuming random sampling from populations with normal, rectangular, and exponential distributions. They emphasize the importance of the assumption one makes about the shape of the underlying distribution in applying statistical methods and about the randomness of sampling (the latter especially in the case of small samples). Later, Pearson [15] described this paper as having 'some of the character of a research report, putting on record a number of lines of inquiry, some of which had not got very far. The way ahead was open; for example, five different methods of approach were suggested for the test of the hypothesis that two different samples came from normal populations having a common mean!' (p. 463).

Neyman and Pearson versus Fisher

As Macdonald [6] has pointed out, both the Fisherian and Neyman–Pearson approaches to statistical inference were concerned with establishing that an observed effect could not plausibly be attributed to sampling error. Perhaps because of this commonality, the blending of the ideas of Fisher with those of Neyman and Pearson has been so thorough, and so thoroughly assimilated by the now conventional treatment of statistical analysis within psychology, that it is difficult to distinguish the two schools of thought. What is generally taught to psychology students in introductory courses on statistics and experimental design makes little, if anything, of this distinction. Typically, statistical analysis is presented as an integrated whole and who originated specific ideas is not stressed. Seldom is it pointed out that the Fisherian approach to statistical analysis and that of Neyman and Pearson were seen by their proponents to be incompatible in several ways and that the rivalry between these pioneers is a colorful chapter in the history of applied statistics. An account of the disagreements between Fisher and Karl Pearson, which were especially contentious, and how they carried over to the relationship between Fisher and Neyman and Egon Pearson has been told with flair by Salsburg [16].

Neyman and Pearson considered Fisher’s method of hypothesis testing, which posed questions that sought yes–no answers – yes, the hypothesis under test is rejected, no it is not – to be too limited. ‘It is indeed obvious, upon a little consideration, that the mere fact that a particular sample may be expected to occur very rarely in sampling from Π would not in itself justify the rejection of the hypothesis that it had been so drawn, if there were no other more probable hypotheses conceivable’ [10, p. 178]. They proposed an approach to take account of how the weight of evidence contributes to the relative statistical plausibility of each of two mutually exclusive hypotheses.² So, in distinction from Fisher’s yes–no approach, Neyman and Pearson’s may be characterized as either–or, because it leads to a judgment in favor of one or the other of the candidate hypotheses. ‘[I]n the great majority of problems we cannot so isolate the relation of $\sum$ to Π ; we reject Hypothesis A not merely because $\sum$ is of rare occurrence, but because there are other hypotheses as to the origin of $\sum$ which it seems more reasonable to accept’ [10, p. 183].

Neyman and Pearson’s approach to statistical testing differed from that of Fisher in other respects as well. Fisher prohibited acceptance of the null hypothesis (the hypothesis of no difference between two samples, or no effect of an experimental manipulation); if the results did not justify rejection of the null hypothesis, the most that could be said was that the null hypothesis could not be rejected. (One of the concerns that have been expressed about the effect of this aspect of null-hypothesis testing is that too often ‘failure’ to reject the null hypothesis has been equated, inappropriately, with failure of a research effort.) The Neyman–Pearson approach permitted acceptance of either of the hypotheses under consideration, including the null if it was one of them, although it provided for making the acceptance (and hence erroneous acceptance) of one of the hypotheses more difficult than acceptance of the other. Other distinguishing features of the Neyman–Pearson approach include the distinction between error types, the conception of sample spaces, the pre-experiment specification of decision criteria, and the notion of the power of a test.

As to the kinds of conclusions that can be drawn from the results of statistical tests, Neyman and Pearson describe them as ‘rules of behaviour’, and they explicitly contrast this with the idea that one can take the results as indicative of the probability that a hypothesis of interest is true or false. In the

first of two 1933 papers, Neyman and Pearson [12] address the question: ‘Is it possible that there are any efficient tests of hypotheses based upon the theory of probability, and if so, what is their nature?’ (p. 290). Their answer is a carefully qualified yes. ‘Without hoping to know whether each separate hypothesis is true or false, we may search for rules to govern our behaviour with regard to them, in following which we insure that, in the long run of experience, we shall not be too often wrong. Here, for example, would be such a “rule of behaviour”: to decide whether a hypothesis, H , of a given type be rejected or not, calculate a specified character, x , of the observed facts; if $x > x_0$ reject H , if $x \leq x_0$ accept H . Such a rule tells us nothing as to whether in a particular case H is true when $x \leq x_0$ or false when $x > x_0$. But it may often be proved that if we behave according to such a rule, then in the long run we shall reject H when it is true not more, say, than once in a hundred times, and in addition we may have evidence that we shall reject H sufficiently often when it is false’ (p. 291).

Error Types and Level of Significance

Neyman and Pearson recognized that there are two possible ways to be right, and two possible ways to be wrong, in drawing a conclusion from a test, and that the two ways of being right (wrong) may not be equally desirable (undesirable). In particular, they stressed that deciding in favor of H_0 when H_1 is true may be a more (or less) acceptable error than deciding in favor of H_1 when H_0 is correct. ‘These two sources of error can rarely be eliminated completely; in some cases it will be more important to avoid the first, in others the second. . . From the point of view of mathematical theory all that we can do is to show how the risk of the errors may be controlled and minimized. The use of these statistical tools in any given case, in determining just how the balance should be struck, must be left to the investigator’ [12, p. 296]. The idea that the main purpose of statistical testing is to identify and learn from error has been expounded in some detail in [7].

Assuming that in most cases of hypothesis testing the two types of error would not be considered equally serious, Neyman and Pearson defined as ‘the error of the first kind’ (generally referred to as Type I error) the error that one would most wish to avoid. ‘The first demand of the mathematical theory is to

deduce such test criteria as would ensure that the probability of committing an error of the first kind would equal (or approximately equal, or not exceed) a preassigned number α , such as $\alpha = 0.05$ or 0.01 , etc. This number is called the level of significance' [9, p. 161].

It is important to stress that α is a conditional probability, specifically the probability of rejecting H_0 – here referring to the null hypothesis in the sense of the hypothesis under test, not necessarily the hypothesis of no difference – conditional on its being true. And its use is justified only when certain assumptions involving random sampling and the parameters of the distributions from which the sampling is done are met. This conditional-probability status of α is often not appreciated and it is treated as the absolute probability of occurrence of a Type I error. But, by definition, a Type I error can be made only when H_0 is true; the unconditional probability of the occurrence of a Type I error is the product of the probability that H_0 is true and the probability of a Type I error given that it is true.

A similar observation pertains to Type II error (failure to reject H_0 when it is false, i.e., failure to accept H_1 when it is true), which, by definition, can be made only when H_0 is false. The probability of occurrence of a Type II error, conditional on H_0 being false, is usually referred to as β (beta), and the unconditional probability of a Type II error is the product of β and the probability that H_0 is false. Computing the absolute unconditional probabilities of Type I and Type II errors generally is not possible, because the probability of H_0 being true (or false) is not known and, indeed, whether to behave as though it were true, to use Neyman and Pearson's term, is what one wants to determine by the application of statistical procedures. Failure to recognize the conditionality of α and β has led to much confusion in the interpretation of results of statistical techniques [14].

Sample Spaces and Critical Areas

Neyman and Pearson conceptualize the outcome of an experiment in terms of the sample spaces that represent the possible values a specified statistic could take under each of the hypotheses of interest. A point in a sample space represents a particular experimental outcome, if the associated hypothesis is true. To test a hypothesis, one divides the sample

space for that hypothesis into two regions and then applies the rule of accepting the hypothesis if the statistic falls in one of these regions and rejecting it if it falls in the other. In null-hypothesis testing, the convention is to define a region, known as the **critical region**, and to reject the hypothesis if the statistic falls in that region.

The situation may be represented as in Figure 1. Each distribution represents the theoretical distribution – the sample space – of some statistic assuming the specified hypothesis is true. The vertical line (decision criterion) represents the division of the space into two regions, the critical region being to the right of the line.³ The area under the curve representing H_0 and to the right of the criterion represents

Figure 1 In panel a, the distribution to the left represents the distribution under H_0 ; that to the right represents the distribution under H_1 . The area under the H_0 distribution and to the right of the decision criterion represents α , the probability of a Type I error conditional on H_0 being true; that under the H_1 distribution and to the left of the criterion represents β , the probability of a Type II error conditional on H_1 being true; the area under the H_1 distribution and to the right of the criterion, $1 - \beta$, is said to be the power of the test, which is the probability of deciding in favor of H_1 conditional on its being true. One decreases the conditional probability of a Type I error by moving the decision to the right, but in doing so, one necessarily increases the conditional probability of a Type II error. Panel b shows the situation assuming a much greater overlap between the two distributions, illustrating that a greater degree of overlap means necessarily a greater error rate. In this case, holding the decision criterion so as to keep the conditional probability of a Type I error constant means greatly increasing the conditional probability of a Type II error

the probability of a Type I error on the condition that H_0 is true; the area under the curve representing H_1 and to the left of the decision criterion represents the probability of a Type II error, on the condition that H_1 is true. As is clear from the figure, given the distributions shown, the probability of a Type I error, conditional on H_0 being true, can be decreased only at the expense of an increase in the probability of a Type II error, conditional on H_1 being true.

Figure 1 has been drawn to represent cases in which the theoretical distributions of H_0 and H_1 overlap relatively little (a) and relatively greatly (b). Obviously, the greater the degree of overlap, the more a stringent criterion for minimizing the conditional probability of a Type I error will cost in terms of allowance of a high conditional probability of a Type II error. We should also note that, as drawn, the figures show the distributions having the same variance and indeed the same Gaussian shape. Such are the default assumptions that are often made in null-hypothesis testing; however, the theoretical distributions used need not be Gaussian, and procedures exist for taking unequal variances into account.

Neyman and Pearson [12] devote most of their first 1933 paper to a discussion of the nontrivial problem of specifying a ‘best critical region’ for controlling Type II error, for a criterion that has been selected to yield a specified (typically small) conditional probability of a Type I error. Such a selection must depend, of course, on what the alternative hypothesis(es) is (are). When there are more alternative hypotheses than one, the best critical region with regard to one of the alternative hypotheses will not generally be the best critical region with respect to another. Neyman and Pearson show that in certain problems it is possible to specify a ‘common family of best critical regions for H_0 with regard to the whole class of admissible alternative hypotheses’ (p. 297). They develop procedures for identifying best critical regions in the sense of maximizing the probability of accepting H_1 when it is true, given a fixed criterion for erroneously rejecting H_0 when it is true.

Power

In setting the decision criterion so as to make the conditional probability of a Type I error very small, one typically ensures that the conditional probability of a Type II error, β , is relatively large, which means

that the chance of failing to note a real effect, if there is one, is fairly high. Neyman and Pearson [13] define the **power** of a statistical test with respect to the alternative hypothesis as $1-\beta$, which is the probability of detecting an effect (rejecting the null) if there is a real effect to be detected (if the null is false).

The power of a statistical test is a function of three variables, as can be seen from Figure 1: the **effect size** (the difference between the means of the distributions), relative variability (the variance or standard deviation of the distributions), and the location of the decision criterion. Often, sample size is mentioned as one of the determinants of power, but this is because the relative variability of a distribution decreases as sample size is increased. Variability can be affected in other ways as well (*see Power*).

Statistical Tests and Judgment

In view of the tendency of some textbook writers to present hypothesis testing procedures, including those of Neyman and Pearson, as noncontroversial formulaic methods that can be applied in cook-book fashion to the problem of extracting information from data, it is worth noting that Neyman and Pearson were sensitive to the need to exercise good judgment in the application of statistical methods to the testing of hypotheses and they characterized the methods as themselves being aids to judgment; they would undoubtedly have been appalled at how the techniques they developed are sometimes applied with little thought as to whether they are really appropriate to the situation and the results interpreted in a categorical fashion.

In general, Neyman and Pearson saw statistical tests as attempts to quantify commonsense notions about the interpretation of probabilistic data. ‘In testing whether a given sample, $\sum$, is likely to have been drawn from a population Π , we have started from the simple principle that appears to be used in the judgments of ordinary life – that the degree of confidence placed in an hypothesis depends upon the relative probability or improbability of alternative hypotheses. From this point of view any criterion which is to assist in scaling the degree of confidence with which we accept or reject the hypothesis that $\sum$ has been randomly drawn from Π should be one which decreases as the probability (defined in some definite manner) of alternative hypotheses becomes

relatively greater. Now it is of course impossible in practice to scale the confidence with which we form a judgment with any single numerical criterion, partly because there will nearly always be present certain *a priori* conditions and limitations which cannot be expressed in exact terms. Yet though it may be impossible to bring the ideal situation into agreement with the real, some form of numerical measure is essential as a guide and control' [11, p. 263].

So, while Neyman and Pearson argue the need for quantitative tests, they stress that they are to be used to aid judgment and not to supplant it. '[T]ests should only be regarded as tools which must be used with discretion and understanding, and not as instruments which in themselves give the final verdict' [10, p. 232]. Again, 'The role of sound judgment in statistical analysis is of great importance and in a large number of problems common sense may alone suffice to determine the appropriate method of attack' [12, p. 292].

They note, in particular, the need for judgment in the interpretation of likelihood ratios, the introduction of which they credit to Fisher [2]. The likelihood ratio is the ratio of the probability of obtaining the sample in hand if H_1 were true to the probability of obtaining the sample if H_0 were true. But, the likelihood ratio is to be weighed along with other, not necessarily numerical considerations in arriving at a conclusion. 'There is little doubt that the criterion of likelihood is one which will assist the investigator in reaching his final judgment; the greater be the likelihood of some alternative Hypothesis A' (not ruled out by other considerations), compared with that of A, the greater will become his hesitation in accepting the latter. It is true that in practice when asking whether Σ can have come from Π , we have usually certain *a priori* grounds for believing that this may be true, or if not so, for expecting that Π' differs from Π in certain directions only. But such expectations can rarely be expressed in numerical terms. The statistician can balance the numerical verdict of likelihood against the vaguer expectations derived from *a priori* considerations, and it must be left to his judgment to decide at what point the evidence in favour of alternative hypotheses becomes so convincing that Hypothesis A must be rejected' [10, p. 187].

Often Neyman and Pearson speak of taking *a priori* beliefs into account in selecting testing procedures or interpreting the results of tests. They

sometimes note that more than one approach to statistical testing can be taken with equal justification, making the choice somewhat a matter of personal taste. And they emphasize the need for discretion or an 'attitude of caution' in the drawing of conclusions from the results of tests.

They viewed statistical analysis as only one of several reasons that should weigh in an investigator's decision as to whether to accept or reject a particular hypothesis, and noted that the combined effect of those reasons is unlikely to be expressible in numerical terms. 'All that is possible for [an investigator] is to balance the results of a mathematical summary, formed upon certain assumptions, against other less precise impressions based upon *a priori* or *a posteriori* considerations. The tests themselves give no final verdict, but as tools help the worker who is using them to form his final decision; one man may prefer to use one method, a second another, and yet in the long run there may be little to choose between the value of their conclusions' [10, p. 176].

Neyman and Pearson give examples of situations in which they would consider it reasonable to reject a hypothesis on the basis of common sense despite the outcome of a statistical test favoring acceptance. They stress the importance of a 'clear understanding [in the mind of a user of a statistical test] of the process of reasoning on which the test is based' [10, p. 230], and note that that process is an individual matter: 'we do not claim that the method which has been most helpful to ourselves will be of greatest assistance to others. It would seem to be a case where each individual must reason out for himself his own philosophy' [10, p. 230]. In sum, Neyman and Pearson presented their approach to statistical hypothesis testing in considerably less doctrinaire terms than methods of hypothesis testing are often presented today.

Other Sources

Other sources of information on the Neyman–Pearson school of thought regarding statistical significance testing and the differences between it and the Fisherian school include [1, 3, 4, 7], and [8].

Notes

1. Neyman and Pearson use a variety of letters and subscripts to designate hypotheses under test. Except

when quoting Neyman and Pearson, I here use H_0 and H_1 to represent respectively the main (often null) hypothesis under test and an alternative, incompatible, hypothesis. In practice, H_1 is often the negation of H_0 .

2. In [11], Neyman and Pearson distinguish between a simple hypothesis (e.g., ‘that $\sum$ has been drawn from an exactly defined population Π ’) and a composite hypothesis (e.g., ‘that $\sum$ has been drawn from an unspecified population belonging to a clearly defined subset ω of the set Ω ’). The distinction is ignored in this article because it is not critical to the principles discussed.
3. In ‘two-tailed’ testing, appropriate when the alternative hypothesis is that there is an effect (e.g., a difference between means), but the direction is not specified, the critical region can be composed of two subregions, one on each end of the distributions.

Nightingale, Florence

Born: May 12, 1820, in Florence, Italy.

Died: August 13, 1910, in London, England.

Florence Nightingale was born into a wealthy English family early in the nineteenth century and was educated at home by her father. That education included mathematics at some level. She continued her studies of mathematics under James Joseph Sylvester. She was also later influenced by the work of **Quetelet**, who was already well known for the application of statistical methods to data from a variety of fields (see [1] for the influence of Quetelet's writing and a short biography of Nightingale).

Nightingale received her initial training in nursing in Egypt, followed by experience in Germany and France. On returning to England, she took up the position of Superintendent of the *Establishment for Gentlewomen during Illness*, on an unpaid basis.

When the Crimean War broke out in 1854, Nightingale was sent by the British Secretary of War

to Turkey as head of a group of 38 nurses. *The Times* had published articles on the poor medical facilities available to British soldiers, and the introduction of nurses to military hospitals was hoped to address the problem. Nightingale was disturbed by the lack of sanitary conditions and fought the military establishment to improve the quality of care. Most importantly to statistics, she collected data on the causes of death among soldiers and used her connections to publicize her results. She was able to show that soldiers were many times more likely to die from illnesses contracted as a result of poor sanitation in the hospitals or from wounds left untreated than to die from enemy fire. To illustrate her point, she plotted her data in the form of polar area diagrams, whose areas were proportional to the cause of deaths. Such a diagram is shown below (Figure 1), and can be found in [2]. Diagrams such as this have since been referred to as *Coxcombs*, although Small [3] has argued that Nightingale used that term to refer to the collection of such graphics. This graphic was published 10 years before the famous graphic by Minard on the size of Napoleon's army in the invasion of Russia. Unlike

The area of the medium, light, and dark gray wedges are each measured from the center as the common vertex.

The medium wedges measured from the center of the circle represent area for area the deaths from Preventable or Mitigable Zymotic Diseases, the light wedges measured from the center the deaths from wounds, & the dark wedges measured from the center the deaths from all other causes.

Figure 1 Causes of death among military personnel in the Crimean War. (The figure was adapted from <http://www.florence-nightingale-avenging-angel.co.uk/Coxcomb.htm>)

2 Nightingale, Florence

Minard's graphic, it carries a clear social message and played an important role in the reform of military hospitals. It represents an early, though certainly not the first, example of the use of statistical data for social change.

Among other graphics, Nightingale created a simple line graph that showed the death rates of civilian and military personnel during peacetime. The data were further broken down by age. The implications were unmistakable and emphasize the importance of controlling confounding variables. Such a graph can be seen in [3].

Because of her systematic collection of data and use of such visual representations, Nightingale played an important role in the history of statistics. Though she had little use for the theory of statistics, she was influential because of her ability to use statistical data to influence public policy.

Nightingale was elected as the first female Fellow of the Royal Statistical Society in 1858, and was made an honorary member of the American Statistical Association, in 1874. During the 1890s she worked unsuccessfully with **Galton** on the establishment of a Chair of Statistics at Oxford.

For many years of her life she was bed-ridden, and she died in 1910 in London, having published

over 200 books, reports, and pamphlets. Additional material on her life can be found in a paper by Conquest in [4].

Nonequivalent Group Design

A nonequivalent group design is used to estimate the relative effects of two or more treatment conditions. In the simplest case, only two treatment conditions are compared. These two conditions could be alternative interventions such as a novel and a standard treatment, or one of the treatment conditions could be a control condition consisting of no intervention. The participants in a nonequivalent group design can be either individuals or aggregates of individuals, such as classrooms, communities, or businesses. Each of the treatments being compared is given to a different group of participants. After the treatment conditions are implemented, the relative effects of the treatments are assessed by comparing the performances across the groups on an outcome measure.

The nonequivalent group design is a quasi-experiment (as opposed to a randomized experiment) (see **Quasi-experimental Designs**) because the participants are assigned to the treatment conditions nonrandomly. Assignment is nonrandom, for example, when participants self-select the treatments they are to receive on the basis of their personal preferences. Assignment is also nonrandom when treatments are assigned by administrators on the basis of what is most convenient or some other nonrandom criterion. Nonequivalent group designs also arise when treatments are assigned to preexisting groups of participants that were created originally for some other purpose without using random assignment.

Differences in the composition of the treatment groups are called *selection differences* [7]. Because the groups of participants who receive the different treatments are formed nonrandomly, selection differences can be systematic and can bias the estimates of the treatment effects. For example, if the participants in one group tend to be more motivated than those in another, and if motivation affects the outcome that is being measured, the groups will perform differently even if the two treatments are equally effective. The primary task in the analysis of data from a nonequivalent group design is to estimate the relative effects of the treatments while taking account of the potentially biasing effects of selection differences.

A variety of statistical methods have been proposed for taking account of the biasing effects

of selection differences [3], [8]. The most common techniques are change-score analysis, **matching** or blocking (using either **propensity scores** or other covariates), **analysis of covariance** (with or without correction for unreliability in the covariates), and selection-bias modeling. These methods all require that one or more pretreatment measures have been collected. In general, the best pretreatment measures are those that are operationally identical to the outcome (i.e., posttreatment) measures. The statistical methods differ in how they use pretreatment measures to adjust for selection differences. Change-score analysis assumes that the size of the average posttreatment difference will be the same as the size of the average pretreatment difference in the absence of a treatment effect. Matching and blocking adjusts for selection differences by comparing participants who have been equated on their pretreatment measures from the treatment conditions. Analysis of covariance is similar to matching, except that equating is accomplished mathematically rather than by physical pairings. Unreliability in the pretreatment measures can be taken into account in the analysis of covariance using **structural equation modeling** techniques [2]. When there are multiple pretreatment measures, **propensity scores** are often used in either matching or analysis of covariance, where a participant's propensity score is the probability that the participant is in one rather than another treatment condition, which is estimated using the multiple pretreatment measures [6]. Selection-bias modeling corrects the effects of selection differences by modeling the nonrandom selection process [1].

Unfortunately, there is no guarantee that any of these or any other statistical methods will properly remove the biases due to selection differences. Each method imposes different assumptions about the effects of selection differences, and it is difficult to know which set of assumptions is most appropriate in any given set of circumstances. Typically, researchers should use multiple statistical procedures to try to 'bracket' the effects of selection differences by imposing a range of plausible assumptions [5]. Researchers can often improve the credibility of their results by adding design features (such as pretreatment measures at multiple points in time and nonequivalent dependent variables) to create a pattern of outcomes that cannot plausibly be explained as a result of selection differences [4]. In addition, because uncertainty about the size of treatment effects

2 Nonequivalent Group Design

is reduced to the extent selection differences are small, researchers should strive to use groups (such as cohorts) that are as initially similar as possible. Nonetheless, even under the best of conditions, the results of nonequivalent group designs tend to be less credible than the results from randomized experiments, because random assignment is the optimal way to make treatment groups initially equivalent.

Nonlinear Mixed Effects Models

Linear mixed-effects (LME) models were developed to model hierarchical (or nested) data. However, before the publication of [2], methods for estimating LME models were not widely available to handle hierarchical data where the observations within a subcategory (often subject) are not equally correlated. This situation usually arises because the observations have been taken over time. This type of hierarchical data is often referred to as growth curve, longitudinal, or (more generally) repeated measures data. We will begin with a quick review of LME and nonlinear regression models to set up ideas and notation.

Linear Mixed-effects Models (LME)

Example: Heights of Girls

The Berkeley growth data [5] includes heights of boys and girls measured between ages 1 to 18 years. In Figure 1, we show a subset of the data for the girls over a range of ages where one might postulate a linear model for the relationship between age and height, for example:

$$y_{ij} = \beta_1 + \beta_2 \text{age}_j + e_{ij} \quad i = 1, \dots, M \quad (1)$$

where M is the number of subjects, y_{ij} is the j th height on the i th subject, β_1 is the intercept, age_j is the j th age, β_2 is the slope for age, e_{ij} is the error term for the j th age for the i th subject.

LME Modeling

We might be tempted to fit the model described in 1 to the data relating to heights of girls. However, the data do not fulfill the assumptions of the typical regression model, that is, $\text{Cov}(e_{ij}, e_{kl}) = 0$ except when $i = k$ and $j = l$. The error terms will not be independent since some come from the same subject and some come from different subjects. In other words, this data has a hierarchical structure that we must take in to account. One additional complication is that the error terms within subject may not be equally correlated since they are observed over time (see **Linear Multilevel Models**).

Figure 1 Heights of 27 girls measured at 8.5, 9, 9.5, 10, and 10.5 years

Figure 1 indicates that the intercept and may be the slope will vary across subjects. We can modify the model to accommodate this as

$$y_{ij} = \beta_{i,1} + \beta_{i,2} \text{age}_j + e_{ij} \quad i = 1, \dots, M \quad (2)$$

Where $\beta_{i,1}$ is the intercept for the i th subject and $\beta_{i,2}$ is the slope for age for the i th subject.

We still have the problem of the dependence of the error terms plus we have a model where the number of parameters grows as the number of subjects does. Common assumptions for the error terms are normality and conditional independence, that is, within subjects, the errors are independent. We write this as $\mathbf{e}_i \sim \mathcal{N}(\mathbf{0}, \sigma^2 \mathbf{I})$ where $\mathbf{e}_i$ is the vector of all the error terms for the i th subject and $\mathbf{I}$ is the identity matrix. Note that the assumption of **conditional independence** is a working assumption that we know may be violated. We will address this issue later in the Section ‘Parameter estimation’.

A popular approach to reducing the number of parameters is to assume that the subjects are a random sample from some underlying population of subjects and that the parameter values for the subjects follow a distribution. A typical choice is

$$\begin{bmatrix} \beta_{i,1} \\ \beta_{i,2} \end{bmatrix} \sim \mathcal{N}(\boldsymbol{\mu}, \mathbf{D}) \quad (3)$$

where $\boldsymbol{\mu}^T = [\mu_1, \mu_2]$ and where μ_1 and μ_2 are the mean (fixed) intercept and slope values for the population of subjects and where $\mathbf{D}$ is a 2×2 covariance

2 Nonlinear Mixed Effects Models

matrix. This assumed distribution on the parameters makes this a mixed-effects model. Models of this type are also commonly called hierarchical, two-stage, empirical-Bayes, growth-curve (*see Growth Curve Modeling*), and multilevel-linear model (*see Linear Multilevel Models*).

Parameter Estimation

Typically, we estimate the fixed effects and variance parameter by computing the marginal distribution of the data by integrating out the random effects. This solves the problem of too many parameters. The resulting distribution has the form

$$\mathbf{y}_i \sim \mathcal{N}(\mathbf{X}_i \boldsymbol{\mu}, \boldsymbol{\Sigma}_i) \quad \text{where } \boldsymbol{\Sigma}_i = \mathbf{Z}_i \mathbf{D} \mathbf{Z}_i^T + \sigma^2 \mathbf{I} \quad (4)$$

and where $\mathbf{Z}_i$ is the design matrix for the random effects and $\mathbf{X}_i$ is the design matrix for the fixed effects (for individual i). In our example they are the same:

$$\mathbf{X}_i = \mathbf{Z}_i = \begin{bmatrix} 1 & 8.5 \\ 1 & 9.0 \\ 1 & 9.5 \\ 1 & 10.0 \\ 1 & 10.5 \end{bmatrix} \quad \text{for all } i \quad (5)$$

The fixed effects ($\boldsymbol{\mu}$) and variance components ($\mathbf{D}$ and σ) are estimated by maximizing the likelihood of the data under this marginal model (4). The marginal variance–covariance matrix $\boldsymbol{\Sigma}_i$ has a rich structure that depends on $\mathbf{D}$ and $\mathbf{Z}$ and that may be sufficient to provide accurate inference for the fixed effects even if our assumption of conditional independence within subject (the $\sigma^2 \mathbf{I}$ term in 4) is not valid. If the term $\mathbf{Z}_i \mathbf{D} \mathbf{Z}_i^T$ is not sufficient to model the marginal variance–covariance structure, it may be necessary to assume a more complex within-subject correlation model. For example $\mathbf{e}_i \sim \mathcal{N}(\mathbf{0}, \sigma^2 \boldsymbol{\Lambda})$, where $\boldsymbol{\Lambda}$ is a correlation matrix corresponding to an autoregressive model.

While this approach requires that $\mathbf{D}$ must be specified and estimated, inference about the fixed effects will not be sensitive to misspecification of $\mathbf{D}$ if the marginal distribution of $\mathbf{y}_i$ is rich enough. This should also hold for sensitivity to the assumption of conditional independence within subject. Since the marginal distribution for LME models has a closed form, the theory for finding **maximum likelihood** and restricted maximum likelihood (*see Maximum Likelihood Estimation*) is straightforward [3]. In

practice, one would use existing software packages to do the estimation.

If estimates for the random effects are desired, the best linear unbiased predictors (BLUPs) are used where ‘Best’ in this case means minimum squared error of prediction (or loss). The BLUPs are also the empirical-Bayes predictors or posterior means of the random effects (*see Random Effects in Multivariate Linear Models: Prediction*).

Nonlinear Regression

Our first task is to define the class of **nonlinear regression model**. Let us consider linear regression models first (*see Multiple Linear Regression*). The term linear regression has two common meanings. The first is straight line regression where the model has the form

$$y_j = \beta_1 + \beta_2 x_j + e_j \quad (6)$$

The subscript j indexes observations as in equation (1). We reserve the subscript i for subjects used in the next section.

The second meaning is a linear model that may, for instance, have additional polynomial terms or terms for groups, for example,

$$y_j = \beta_1 + \beta_2 \text{tmt}_j + \beta_3 x_j + \beta_4 x_j^2 + e_j \quad (7)$$

where tmt_j would be, for example, 0 for observations in the control group and 1 for observations in the treated group.

The definition of a linear model is one that can be written in the following form

$$y_j = \sum_k \beta_k x_{kj} + e_j \quad (8)$$

where the β s are the only parameters to be estimated. Equations 6 and 7 can be written in this form and are linear but the following nonlinear regression model is not linear

$$y_j = \beta_1 + \beta_2 x_j^{\beta_3} + e_j \quad (9)$$

A second definition of a linear model is a model for which the derivative of the right-hand side of the model equation with respect to any individual parameter contains no parameters at all.

Nonlinear models are most commonly used for data that show single or double asymptotes, inflection

points, and other features not well fit by polynomials. Often, there is no mechanistic interpretation for the parameters (other than intercepts, asymptotes, inflection points, etc.), they simply describe the relationship between the predictor and outcome variables via the model function. There are certain nonlinear models where scientists have attempted to interpret the parameters as having physical meaning. One such class of models is compartment models [1].

Equation 9 is a simple (fixed effects only) nonlinear regression model that can be used for data where there is no nested structure but where a linear model does not adequately describe the relationship between the predictors and the outcome variable. The general form of the model for the j th observation is

$$y_j = f(\boldsymbol{\beta}, \mathbf{x}_j) + e_j \quad e_j \sim \mathcal{N}(0, \sigma^2) \quad (10)$$

where $f(\boldsymbol{\beta}, \mathbf{x}_j) = \beta_1 + \beta_2 x_j^{\beta_3}$ is the assumed model with parameters $\boldsymbol{\beta}$ that relates the mean response y_j to the predictor variables $\mathbf{x}_j$. The error terms are assumed to be independent. Note that $\mathbf{x}_j$ can contain more than one predictor variable although in this model there is only one. The parameters $\boldsymbol{\beta}$ are typically estimated via nonlinear least squares [1].

Nonlinear Mixed-effects Models

Nonlinear mixed-effects (NLME) models are used when the data have a hierarchical structure as described above for LME models but where a nonlinear function is required to adequately describe the relationship between the predictor(s) and the outcome variable.

Example: Tongue Lengths

Figure 2 shows measured tongue length from magnetic resonance images for 14 children [6]. Note that in this data set, not every subject has been measured at each age. An important feature of mixed effects models (linear and nonlinear) is that all subjects do not have to be measured at the same time points or the same number of times.

One model that fits these data well is the asymptotic regression model. It has many formulations but the one we have chosen is

$$y_{ij} = \alpha - \beta \exp(-\gamma \text{age}_{ij}) + e_{ij} \quad (11)$$

Figure 2 Tongue length at various ages for 14 children. Each child's data are connected by a line

In this version, α is the asymptote as age goes to infinity, β is the range between the response at age = 0 and α , and γ controls the rate at which the curve achieves its asymptote.

Once again it is sensible to postulate a model that includes parameters that are specific to subject. It turns out that in this case only α needs to vary between subjects. The model then takes on the following form:

$$y_{ij} = \alpha_i - \beta \exp(-\gamma \text{age}_{ij}) + e_{ij} \quad (12)$$

We model the parameters as random in the population of subjects with a fixed mean μ and assume $\alpha_i \sim \mathcal{N}(\mu, \sigma_\alpha^2)$ and $e_i \sim \mathcal{N}(\mathbf{0}, \sigma^2 \mathbf{I})$.

It is also possible to add additional predictors such as gender. If gender is expected to affect the intercept, we can rewrite the model for the intercepts by modifying the model for the random intercepts $\alpha_i \sim \mathcal{N}(\mu_1 + \mu_2 \text{gender}, \sigma_\alpha^2)$ or equivalently by modifying the model for the responses (but not both)

$$y_{ij} = \alpha_i + \mu_2 \text{gender} - \beta \exp(-\gamma \text{age}_{ij}) + e_{ij} \quad (13)$$

Parameter Estimation

Just as in the LME case, estimation for NLME models is accomplished by finding the maximum likelihood estimates that correspond to the marginal distribution for the data. However, unlike in the linear case, there is usually no closed form expression

for the marginal distribution of an NLME model. Thus, direct maximum likelihood estimation requires either numerical or Monte Carlo integration (*see Markov Chain Monte Carlo and Bayesian Statistics*). Alternatively, estimation can be accomplished using approximate maximum likelihood or restricted maximum likelihood [3].

We can write down an approximate marginal variance covariance–matrix which has the form

$$\hat{\Sigma}_i = \hat{\mathbf{Z}}_i \hat{\mathbf{D}} \hat{\mathbf{Z}}_i^T + \hat{\sigma}^2 \mathbf{I}. \quad (14)$$

Here $\hat{\mathbf{Z}}_i$ is the derivative matrix of the right-hand side of the subject specific model (12) with respect to the random effects. Unlike in the linear model, it will, in general, depend on the estimated parameter values [3]. The term $\hat{\mathbf{Z}}_i \hat{\mathbf{D}} \hat{\mathbf{Z}}_i^T$ may capture the marginal covariance of the data and assuming independence within subject may still result in a valid inference on the fixed effects. If not (as in this case where only the ‘intercept’ is random and $\mathbf{Z}_i$ is a column vector of 1s), various more general forms for the within-subject covariance can be assumed (as described under LME models above).

The maximum likelihood estimates (and standard errors) for the tongue data main effects are $\hat{\mu} = 12.16(0.65)$, $\hat{\beta} = 4.65(0.57)$, and $\hat{\gamma} = 0.023(0.0069)$. The estimated variance components are $\hat{\sigma}_2 = 0.203$ (standard deviation of the intercepts) and $\hat{\sigma} = 0.478$ (within-subject standard deviation). Figure 3 shows the fitted population average and subject specific curves for the tongue length data. The thick line corresponds to the fitted values when the estimated mean value $\hat{\mu}$ is substituted in for α_i . The lighter lines each correspond to a subject and are computed from the BLUP estimates of α_i . These estimates were obtained using the NLME package for the R statistical software package [4]. There are other packages that implement NLME models, including the SAS procedure NLMIXED (*see Software for Statistical Analyses*).

Testing in NLME models is a bit more complex than in standard regression or **analysis of variance**. Simulation studies have found that likelihood ratio tests perform well for testing for the need for variance components (like adding a random effect) even though they are theoretically invalid because the parameter value being tested is on the edge of the parameter space. Methods for testing fixed

Figure 3 Population average (thick line) and subject level (lighter lines) fitted curves for the tongue length data

effects are still controversial but it is known that LR tests are much too liberal and approximate F tests [3] seem to do a better job. More evaluation is required.

Nonlinear Models

A nonlinear model expresses a relationship between a response variable and one or more predictor variables as a nonlinear function. The stochastic, or random, model is used to indicate that the expected response is obscured somewhat by a random error element. The nonlinear model may be expressed as follows:

$$Y = f(X, \theta) + \varepsilon, \quad (1)$$

where X denotes a vector (perhaps of length one) of independent, or predictor, variables and θ denotes a vector of one or more (unknown) parameters in the model. $f(X, \theta)$ expresses the functional relationship between the expectation of Y , denoted $E(Y)$, and X and θ . That is, $E(Y) = f(X, \theta)$. ε denotes the random error that prevents measurement of $E(Y)$ directly. ε is assumed to have a Gaussian distribution centered upon 0 and with constant variance for each independent observation of Y and X . That is, $\varepsilon \sim N(0, \sigma^2)$.

An example of a nonlinear model is

$$Y = \frac{\theta_1 X}{\theta_2 + X} + \varepsilon, \quad (2)$$

the so-called Michaelis–Menten model. This model can be transformed to a linear form for $E(Y)$, but the error properties of ε usually dictate the use of nonlinear estimation techniques. The Michaelis–Menten model has been used to model the velocity of a chemical reaction as a function of the underlying concentrations. Thus, a mnemonic representation is given by

$$V = \frac{\theta_1 C}{\theta_2 + C} + \varepsilon. \quad (3)$$

A graph of this model is presented in Figure 1:

Here, we see the nonlinear relationship expected between V and C , with $\theta_1 = 30$ and $\theta_2 = 0.5$.

Advantages of Nonlinear Models

An obvious advantage of a nonlinear model is that the methodology allows modeling and prediction of relationships that are more complicated in nature than the familiar linear model. Nonlinear

Figure 1 A Michaelis–Menten model

modeling also allows for special interpretation of parameters. In some cases, the parameters or functions of them describe special attributes of the nonlinear relationship that are apparent in graphs, such as (a) intercepts, (b) asymptotes, (c) maxima, (d) minima, and (e) inflection points. The following graph (Figure 2) demonstrates a graphical interpretation of $\theta = \begin{pmatrix} \theta_1 \\ \theta_2 \end{pmatrix}$ in the Michaelis–Menten model:

This demonstrates that θ_1 is the maximum attainable value, expressed as an asymptote, for V , and θ_2 is the so-called ‘half-dose,’ or the concentration C at which V attains half its theoretical maximum. Another nonlinear model is graphed in Figure 3:

Figure 2 Parameter interpretation in a Michaelis–Menten model

Figure 3 The autocatalytic growth model

The ‘autocatalytic growth model’ postulates that height H cannot exceed its maximum α , that it occurs as an S-shaped curve with inflection point $((\ln \beta)/C, \alpha/2)$, and that the starting height at $T = 0$ is $\alpha/(1 + \beta)$. The formula $H = \alpha/(1 + \beta e^{-CT})$, with its logistic, S-shaped curve, assures that the curve is skew-symmetric about the inflection point.

As we can see, a researcher familiar with data properties through graphs may be able to deduce or find a nonlinear model that reflects desired properties. Another advantage of nonlinear models is that the model can reflect properties based on relevant differential equations. For instance, the autocatalytic growth model is the solution to a specific differential equation. This rate equation states that the growth rate relative to the attained height is proportional to the amount of height yet unattained. In other words, as height approaches its maximum, the growth slows. The differential equation for which $H = \alpha/(1 + \beta e^{-CT})$ is a solution is

$$\frac{dH}{dT} \frac{1}{H} = \frac{C(\alpha - H)}{\alpha}. \quad (4)$$

Often nonlinear models arise when researchers can specify a rate-of-change relationship, which can be expressed as either a single differential equation or as a system of differential equations. Choosing a candidate model can be a creative, enjoyable process in which researchers use their knowledge and experience to find the most promising model for their project.

Parameter Estimation

To estimate the parameters in a proposed nonlinear model $Y = f(X, \theta) + \varepsilon$, data observations must be made on both the response variable Y and its predictors X . The number of observations made is denoted by n , or the ‘sample size.’ An iterative process is often used to find the parameter estimates $\hat{\theta}$. To find the ‘best’ estimates, or the ones likely to be close to the true, unknown θ , the iterative method tries to find the $\hat{\theta}$ that minimizes the sum of squared differences between the n observed Y ’s and the predicted Y ’s, the $\hat{Y}$ ’s. That is, the least-squares solution (see **Least Squares Estimation**) will be the $\hat{\theta}$ that minimizes the sum of squared residuals

$$\sum_{i=1}^n r_i^2 = \sum_{i=1}^n (Y_i - \hat{Y}_i)^2. \quad (5)$$

In other words, the nY_i ’s obtained using the least-squares optimal $\hat{\theta}$ will minimize the sum of squared residuals. There is a vast literature dealing with methods of optimization using computer methods (see **Optimization Methods**). Some techniques developed to minimize $\sum_{i=1}^n r_i^2$ are the steepest-descent or gradient method, the Newton method, the modified Gauss–Newton method, the Marquardt method, and the multivariate secant method. Most of these methods require an initial starting value for $\hat{\theta}$. This can often be obtained through graphical analysis of the data, using any known relationships between a θ component θ_i and graphical properties such as asymptotes, intercepts, and so on.

If there is a linearizing transformation that is not being used due to error distribution considerations (as was the case for the Michaelis–Menten model above), then the linear least-squares solution for the transformed linear model may provide a good starting $\hat{\theta}$. Another possibility might be to use an initial $\hat{\theta}$ from the literature if the model has been used successfully in a previous study.

Since there is not a closed-form solution, a criterion must be chosen to determine when a satisfactory solution has been found and the computer minimization program should stop iterating. Usually, the stopping rule is to abandon searching for a better solution and report the current $\hat{\theta}$ when the reduction of $\sum_{i=1}^n r_i^2$ is small in the most recent step. Sometimes there is difficulty obtaining convergence, with the computer program ‘cycling’ around a potential solution, but not homing in on the best answer due

to technical problems with the method chosen or a poorly chosen starting value. Trying again with a new starting $\hat{\theta}$ or choosing a new iterative optimization technique are obvious suggestions when convergence difficulties occur. This approach will also help ensure that if convergence is reached, then what was found was a true global minimum, and not just a local one.

Confidence Regions

In addition to the point estimate $\hat{\theta}$, which is generally the least-squares solution, it is also desirable to report 95% (or some such high confidence level) confidence regions for θ . Researchers often desire confidence intervals for individual θ_i , the components of θ . Through advanced programming techniques, it is possible to compute exact confidence regions for θ . However, if the sample size is small, then it may be extremely difficult to compute the regions, or the regions themselves may be unsatisfactorily complicated. For example, a 95% exact confidence region for θ may consist of several disjoint, asymmetric areas in R^k , where k is the dimension of θ . Approximate confidence ellipsoids for θ can be computed, along with approximate confidence intervals for the θ_i . The accuracy and precision of these approximate confidence regions depend upon two factors: the estimation properties of the chosen model and the sample size.

Estimation Properties

The accuracy (unbiasedness) and precision (small size) of the approximate confidence ellipsoids and confidence intervals mentioned above depend upon an estimation property of a particular nonlinear model termed ‘close-to-linear behavior.’ As it turns out, a model with close-to-linear behavior will tend to produce good confidence regions and confidence intervals with relatively small sample sizes. Conversely, those models without this behavior may not produce similarly desirable confidence intervals. The properties of various types of nonlinear models have been rigorously studied, and researchers seeking an efficient nonlinear model, which can accomplish accurate inference with small sample sizes, can search the literature of nonlinear models to find a model with desirable estimation properties.

Model Validation

The nonlinear model validation process is similar in some ways to that for linear regression (*see Multiple Linear Regression*). Scatter plots of residuals versus predicted values can be used to detect model fit. Small confidence intervals for the θ_i indicate precision. An important *caveat* is that R^2 , the familiar coefficient of determination from linear regression, is not meaningful in the context of a nonlinear model.

A Fitted Nonlinear Model

To illustrate these points, simulated data, with a sample size of $n = 32$, were generated using the Michaelis–Menten model discussed above:

$$V = \frac{\theta_1 C}{\theta_2 + C} + \varepsilon, \text{ with } \theta_1 = 30, \text{ and } \theta_2 = 0.5. \\ \varepsilon \sim N(0, (1.5)^2) \quad (6)$$

The nonlinear regression program (SAS version 8.02) converged in five iterations to the following estimates:

Parameter	Estimate	Estimated S.E.	Approximate 95% confidence limits	
θ_1	29.36	0.66	28.02	30.70
θ_2	0.44	0.05	0.34	0.54

A graph is presented in Figure 4.

There are some excellent texts dealing with nonlinear models. See, for example, [1], [2], [3], [4], [5], and [6].

Nonparametric Correlation (r_s)

Spearman's Correlation for Ranked Data

Let $(x_1, x_2, \dots, x_n)$ and $(y_1, y_2, \dots, y_n)$ be random samples of sizes n from the two random variables, X and Y . The scale of measurement of the two random variables is at least ordinal and, to avoid problems with ties, ought to be strictly continuous. Rank the data within each variable separately and let $(r_{x1}, r_{x2}, \dots, r_{xn})$ and $(r_{y1}, r_{y2}, \dots, r_{yn})$ represent the ranked data.

Our goal is to correlate the two sets of ranks and obtain a test of significance on that correlation. Spearman provided a formula for this correlation, assuming no ties in the ranks, as

$$r_s = 1 - \frac{6\sum D_i^2}{N(N^2 - 1)}, \quad (1)$$

where D_i is defined as the set of differences between r_{xi} and r_{yi} . Spearman derived this formula (using such equalities as the sum of the first N integers = $N(N + 1)/2$) at a time when calculations were routinely carried by hand. The result of using this formula is exactly the same as applying the traditional **Pearson product-moment correlation** coefficient to the ranked data, and that is the approach commonly used today. The Pearson formula is correct regardless of whether there are tied ranks, whereas the Spearman formula requires a correction for ties.

Example

The Data and Story Library website (DASL) (<http://lib.stat.cmu.edu/DASL/Stories/AlcoholandTobacco.html>) provides data on the average weekly spending on alcohol and tobacco products for each of 11 regions in Great Britain. The data follow in Table 1. Columns 2 and 3 contain expenditures in pounds, and Columns 4 and 5 contain the ranked data for their respective expenditures.

Though it is not apparent from looking at either the alcohol or tobacco variable alone, in a bivariate plot it is clear that Northern Ireland is a major outlier.

Table 1 Expenditures for alcohol and tobacco by region of Great Britain

Region	Alcohol	Tobacco	Rank A	Rank T
North	6.47	4.03	11	9
Yorkshire	6.13	3.76	9	7
Northeast	6.19	3.77	10	8
East Midlands	4.89	3.34	4	4
West Midlands	5.63	3.47	6	5
East Anglia	4.52	2.92	2	2
Southeast	5.89	3.20	7	3
Southwest	4.79	2.71	3	1
Wales	5.27	3.53	5	6
Scotland	6.08	4.51	8	10
Northern Ireland	4.02	4.56	1	11

Similarly, the distribution of alcohol expenditures is decidedly nonnormal, whereas the ranked data on alcohol, like all ranks, is rectangularly distributed.

The Spearman correlation coefficient (r_s) for this sample is 0.373, whereas the Pearson correlation (r) on the raw-score variables is 0.224.

There is no generally accepted method for estimation of the standard error of r_s for small samples. This makes the computation of confidence limits problematic, but with very small samples the width of the confidence interval is likely to be very large in any event. Kendall [1] has suggested that for sample sizes greater than 10, r_s can be tested in the same manner as the Pearson correlation (*see* **Pearson Product Moment Correlation**). For these data, because of the extreme outlier for Northern Ireland, the correlation is not significant using the standard approach for Pearson's r ($p = 0.259$, two tailed) or using a randomization test ($p = 0.252$, two tailed).

There are alternative approaches to rank correlation. See **Nonparametric Correlation (tau)** for an alternative method for correlating ranked data.

Nonparametric Correlation (tau)

Kendall's Correlation for Ranked Data (τ)

Let $(x_1, x_2, \dots, x_n)$ and $(y_1, y_2, \dots, y_n)$ be random samples of sizes n from the two random variables, X and Y . The scale of measurement of the two random variables is at least ordinal and, to avoid problems with ties, ought to be strictly continuous. Rank the data within each variable separately and let $(r_{x1}, r_{x2}, \dots, r_{xn})$ and $(r_{y1}, r_{y2}, \dots, r_{yn})$ represent the ranked data.

Our goal is to correlate the two sets of ranks and obtain a test of significance on that correlation. The correlation coefficient is based on the number of concordant and discordant rankings, or, equivalently, the number of inversions in rank.

We will rank the data separately for each variable and let C represent the number of concordant pairs of observations, which is the number of pairs of observations whose rankings on the two variables are ordered in the same direction. We will let D represent the number of discordant pairs (pairs where the rankings on the two variables are in the opposite direction), and let $S = C - D$. Then

$$\tau = \frac{2S}{n(n-1)}. \quad (1)$$

(It is not essential that we actually do the ranking, though it is easier to work with ranks than with raw scores.)

Example

The Data and Story Library website (DASL) (<http://lib.stat.cmu.edu/DASL/Stories/AlcoholandTobacco.html>) provides data on the average weekly spending on alcohol and tobacco products for each of 11 regions in Great Britain. The data follow. Columns 2 and 3 contain expenditures in pounds, and Columns 4 and 5 contain the ranked data for their respective expenditures as in Table 1.

Though it is not apparent from looking at either the Alcohol or Tobacco variable alone, in a bivariate plot it is clear that Northern Ireland is a major outlier.

Table 1 Alcohol and tobacco expenditures in Great Britain, broken down by region

Region	Alcohol	Tobacco	Rank A	Rank T
North	6.47	4.03	11	9
Yorkshire	6.13	3.76	9	7
Northeast	6.19	3.77	10	8
East Midlands	4.89	3.34	4	4
West Midlands	5.63	3.47	6	5
East Anglia	4.52	2.92	2	2
Southeast	5.89	3.20	7	3
Southwest	4.79	2.71	3	1
Wales	5.27	3.53	5	6
Scotland	6.08	4.51	8	10
Northern Ireland	4.02	4.56	1	11

Similarly, the distribution of Alcohol expenditures is decidedly nonnormal, whereas the ranked data on alcohol, like all ranks, are rectangularly distributed.

There are $n(n-1)/2 = 11(10)/2 = 55$ pairs of rankings. 37 of those pairs are concordant, while 18 are discordant. (For example, Yorkshire ranks lower than the North of England on both Alcohol and Tobacco, so that pair of rankings is concordant. On the other hand, Scotland ranks lower than the North of England on Alcohol expenditures, but higher on Tobacco expenditures, so that pair of rankings is discordant.)

Then

$$C = 37$$

$$D = 18$$

$$S = C - D = 37 - 18 = 19$$

$$\tau = \frac{2S}{N(N-1)} = \frac{38}{110} = 0.345. \quad (2)$$

For these data Kendall's $\tau = 0.345$.

Unlike Spearman's r_s , there is an accepted method for estimation of the standard error of Kendall's τ [1].

$$s_\tau = \sqrt{\frac{2(2N+5)}{9N(N-1)}}. \quad (3)$$

Moreover, τ is approximately normally distributed for $N \geq 10$. This allows us to approximate the sampling distribution of Kendall's τ using the normal approximation.

$$z = \frac{\tau}{s_\tau} = \frac{\tau}{\sqrt{\frac{2(2N+5)}{9N(N-1)}}} = \frac{0.345}{\sqrt{\frac{2(27)}{9(11)(10)}}}$$

2 Nonparametric Correlation (tau)

$$= \frac{0.345}{0.2335} = 1.48. \quad (4)$$

For a two-tailed test $p = .139$, which is not significant.

With a standard error of 0.2335, the **confidence limits** on Kendall's τ , assuming normality of τ , would be

$$\begin{aligned} CI &= \tau \pm 1.96s_\tau = \tau \pm 1.96 \left(\sqrt{\frac{2(2N+5)}{9N(N-1)}} \right) \\ &= \tau \pm 1.96(0.2335) \end{aligned} \quad (5)$$

For our example this would produce confidence limits of $-0.11 \leq t \leq 0.80$.

There are alternative approaches to rank correlation. See **Nonparametric Correlation (r_s)** for an alternative method for correlating ranked data. Kendall's τ has generally been given preference over Spearman's r_s because it is a better estimate of the corresponding population parameter, and its standard error is known.

Nonparametric Item Response Theory Models

Goals of Nonparametric Item Response Theory

Nonparametric item response theory (NIRT) models are used for analyzing the data collected by means of tests and questionnaires consisting of J items. The goals are to construct a scale for the ordering of persons and – depending on the application of this scale – for the items. To attain these goals, test constructors and other researchers primarily want to know whether their items measure the same or different traits, and whether the items are of sufficient quality to distinguish people with relatively low and high standings on these traits. These questions relate to the classical issues of validity (*see* **Validity Theory and Applications**) and reliability, respectively. Other issues of interest are **differential item functioning**, person-fit analysis, and skill identification and cognitive modeling.

NIRT models are most often used in small-scale testing applications. Typical examples are intelligence and personality testing. Most intelligence tests and personality inventories are applied to individuals only once, each individual is administered the same test, and testing often but not necessarily is individual. Another example is the measurement of attitudes, typical of sociological or political science research. Attitude questionnaires typically consist of, say, 5 to 15 items, and the same questionnaire is administered to each respondent in the sample. NIRT is also applied in educational testing, preference measurement in marketing, and health-related quality-of-life measurement in a medical context. See [16] for a list of applications.

NIRT is interesting for at least two reasons. First, because it provides a less demanding framework for test and questionnaire data analysis than parametric item response theory, NIRT is more data-oriented, more exploratory and thus more flexible than parametric IRT; see [7]. Second, because it is based on weaker assumptions than parametric IRT, NIRT can be used as a framework for the theoretical exploration of the possibilities and the boundaries of IRT in general; see, for example, [4] and [6].

Assumptions of Nonparametric IRT Models

The assumptions typical of NIRT models, and often shared with parametric IRT models, are the following:

- *Unidimensionality (UD)*. A unidimensional IRT model contains one **latent variable**, usually denoted by θ , that explains the variation between tested individuals. From a fitting unidimensional IRT model, it is inferred that performance on the test or questionnaire is driven by one ability, achievement, personality trait, or attitude. Multidimensional IRT models exist that assume several latent variables to account for the data.
- *Local independence (LI)*. Let X_j be the random variable for the score on item j ($j = 1, \dots, J$); let x_j be a realization of X_j ; and let $\mathbf{X}$ and $\mathbf{x}$ be the vectors containing J item score variables and J realizations, respectively. Also, let $P(X_j = x_j|\theta)$ be the conditional probability of a score of x_j on item j . Then, a latent variable θ , possibly multidimensional, exists such that the joint conditional probability of J item responses can be written as

$$P(\mathbf{X} = \mathbf{x}|\theta) = \prod_{j=1}^J P(X_j = x_j|\theta). \quad (1)$$

An implication of LI is that for any pair of items, say j and k , their conditional covariance equals 0; that is, $\text{Cov}(X_j, X_k|\theta) = 0$.

- *Monotonicity (M)*. For binary item scores, $X_j \in \{0, 1\}$, with score zero for an incorrect answer and score one for a correct answer, we define $P_j(\theta) \equiv P(X_j = 1|\theta)$. This is the item response function (IRF). Assumption M says that the IRF is monotone nondecreasing in θ . For ordered rating scale scores, $X_j \in \{0, \dots, m\}$, a similar monotonicity assumption can be made with respect to response probability, $P(X_j \geq x_j|\theta)$.

Parametric IRT models typically restrict the IRF, $P_j(\theta)$, by means of a parametric function, such as the logistic. A well-known example is the three-parameter logistic IRF. Let γ_j denote the lower asymptote of the logistic IRF for item j , interpreted as the pseudochance probability; let δ_j denote the location of item j on the θ scale, interpreted as the

2 Nonparametric Item Response Theory Models

difficulty; and let $\alpha_j(>0)$ correspond to the steepest slope of the logistic function, which is located at parameter δ_j and interpreted as the discrimination. Then the IRF of the three-parameter logistic model is

$$P_j(\theta) = \gamma_j + (1 - \gamma_j) \frac{\exp[\alpha_j(\theta - \delta_j)]}{1 + \exp[\alpha_j(\theta - \delta_j)]}. \quad (2)$$

Many other parametric IRT models have been proposed; see [20] for an overview.

NIRT models only impose order restrictions on the IRF, but refrain from a parametric definition. Thus, assumption M may be the only restriction, so that for any two fixed values $\theta_a < \theta_b$, we have that

$$P_j(\theta_a) \leq P_j(\theta_b). \quad (3)$$

The NIRT model based on assumptions UD, LI, and M is the monotone homogeneity model [8]. Assumption M may be further relaxed by assuming that the mean of the J IRFs is increasing, but not each of the individual IRFs [17]. This mean is the test response function, denoted by $T(\theta)$ and defined as

$$T(\theta) = J^{-1} \sum_{j=1}^J P_j(\theta), \text{ increasing in } \theta. \quad (4)$$

Another relaxation of assumptions is that of strict unidimensionality, defined as assumption UD, to essential unidimensionality [17]. Here, the idea is that one dominant trait drives test performance in particular, but that there are also nuisance traits active, whose influence is minor.

In general, one could say that NIRT strives for defining models that are based on relatively weak assumptions while maintaining desirable measurement properties. For example, it has been shown [2] that the assumptions of UD, LI, and M imply that the total score $X_+ = \sum_{j=1}^J X_j$ stochastically orders latent variable θ ; that is, for two values of X_+ , say $x_{+a} < x_{+b}$, and any value t of θ , assumptions UD, LI, and M imply that

$$P(\theta \geq t | X_+ = x_{+a}) \leq P(\theta \geq t | X_+ = x_{+b}). \quad (5)$$

Reference [3] calls (2) a stochastic ordering in the latent trait (SOL). SOL implies that for higher X_+ values the θ s are expected to be higher on average. Thus, (5) defines an ordinal scale for person measurement: if the monotone homogeneity model fits the data, total score X_+ can be used for ordering

persons with respect to latent variable θ , which by itself is not estimated.

The three-parameter logistic model is a special case of the monotone homogeneity model, because it has monotone increasing logistic IRFs and assumes UD and LI. Thus, SOL also holds for this model. The item parameters, γ , δ , and α , and the latent variable θ can be solved from the likelihood of this model. These estimates can be used to calibrate a metric scale that is convenient for equating, item banking, and adaptive testing in large-scale testing [20]. NIRT models are candidates for test construction, in particular, when an ordinal scale for respondents is sufficient for the application envisaged.

Another class of NIRT models is based on stronger assumptions. For example, to have an ordering of items which is the same for all values of θ , with the possible exception of ties for some θ s, it is necessary to assume that the J items have IRFs that do not intersect. This is called an invariant item ordering (IIO, [15]). Formally, J items have an IIO, when they can be ordered and numbered such that

$$P_1(\theta) \leq P_2(\theta) \leq \dots \leq P_J(\theta), \text{ for all } \theta. \quad (6)$$

A set of items that is characterized by an IIO facilitates the interpretation of results from differential item functioning and person-fit analysis, and provides the underpinnings of the use of individual starting and stopping rules in intelligence testing and the hypothesis testing of item orderings that reflect, for example, ordered developmental stages. The NIRT model based on the assumptions of UD, LI, M, and IIO is the double monotonicity model [8].

The generalization of the SOL and IIO properties from dichotomous-item IRT models to polytomous-item IRT models is not straightforward. Within the class of known polytomous IRT models, SOL can only be generalized to the parametric partial credit model [20] but not to any other model. Reference [19] demonstrated that although SOL is not implied by most models, it is a robust property for most tests in most populations, as simulated in a robustness study. For J polytomously scored items, an IIO is defined as

$$E(X_1|\theta) \leq E(X_2|\theta) \leq \dots \leq E(X_J|\theta), \text{ for all } \theta. \quad (7)$$

Thus, the ordering of the mean item scores is the same, except for possible ties, for each value of

θ . IIO can only be generalized to the parametric rating scale model [20] and similarly restrictive IRT models. See [13] and [14] for nonparametric models that imply an IIO.

Because SOL and IIO are not straightforwardly generalized to polytomous-item IRT models, and because these models are relatively complicated, we restrict further attention mostly to dichotomous-item IRT models. More work on the foundations of IRT through studying NIRT has been done, for example, by [1, 3, 4, 6, and 17]. See [8] and [16] for monographs on NIRT.

Evaluating Model-data Fit

Several methods exist for investigating fit of NIRT models to test and questionnaire data. These methods are based mostly on one of two properties of observable variables implied by the NIRT models.

Conditional-association Based Methods

The first observable property is conditional association [4]. Split item score vector $\mathbf{X}$ into two disjoint part vectors, $\mathbf{X} = (\mathbf{Y}, \mathbf{Z})$. Define f_1 and f_2 to be non-decreasing functions in the item scores from $\mathbf{Y}$, and g to be some function of the item scores in $\mathbf{Z}$. Then UD, LI, and M imply conditional association in terms of the covariance, denoted by Cov, as

$$\text{Cov}[f_1(\mathbf{Y}), f_2(\mathbf{Y})|g(\mathbf{Z}) = z] \geq 0, \quad \text{for all } z. \quad (8)$$

Two special cases of (8) constitute the basis of model-data fit methods:

Unconditional inter-item covariances. If function $g(\mathbf{Z})$ selects the whole group, and $f_1(\mathbf{Y}) = X_j$ and $f_2(\mathbf{Y}) = X_k$, then a special case of (8) is

$$\text{Cov}(X_j, X_k) \geq 0, \quad \text{all pairs } j, k; j < k. \quad (9)$$

Negative inter-item covariances give evidence of model-data misfit.

Let $\text{Cov}(X_j, X_k)_{\max}$ be the maximum **covariance** possible given the marginals of the cross table for the bivariate frequencies on these items. Reference [8] defined coefficient H_{jk} as

$$H_{jk} = \frac{\text{Cov}(X_j, X_k)}{\text{Cov}(X_j, X_k)_{\max}}. \quad (10)$$

Equation 9 implies that $0 \leq H_{jk} \leq 1$. Thus, positive values of H_{jk} found in real data support the monotone homogeneity model, while negative values reject the model. Coefficient H_{jk} has been generalized to (1) an item coefficient, H_j , which expresses the degree to which item j belongs with the other $J - 1$ in one scale; and (2) a scalability coefficient, H , which expresses the degree to which persons can be reliably ordered on the θ scale using total score X_+ .

An item selection algorithm has been proposed [8, 16] and implemented in the computer program MSP5 [9], which selects items from a larger set into clusters that contain items having relatively high H_j values with respect to one another – say, $H_j \geq c$, often with $c > 0.3$ (c user-specified) – while unselected items have H_j values smaller than c . Because, for a set of J items, $H \geq \min(H_j)$ [8], item selection produces scales for which $H \geq c$. If $c \geq 0.3$, person ordering is at least weakly reliable [16]. Such scales can be used in practice for person measurement, while each scale identifies another latent variable.

Conditional inter-item covariances. First, define a total score – here, called a *rest score* and denoted R – based on $\mathbf{X}$ as,

$$R_{(-j, -k)} = \sum_{h \neq j, k} X_h. \quad (11)$$

Second, define function $g(\mathbf{Z}) = R_{(-j, -k)}$, and let $f_1(\mathbf{Y}) = X_j$ and $f_2(\mathbf{Y}) = X_k$. Equation 8 implies that,

$$\begin{aligned} \text{Cov}[X_j, X_k | R_{(-j, -k)} = r] &\geq 0, \quad \text{all } j, k; j < k; \\ \text{all } r &= 0, 1, \dots, J - 2. \end{aligned} \quad (12)$$

That is, in the subgroup of respondents that have the same rest score r , the covariance between items j and k must be nonnegative. Equation 12 is the basis of procedures that try to find an item subset structure for the whole test that approximates local independence as good as possible. The optimal solution best represents the latent variable structure of the test data. See the computer programs DETECT and HCA/CCPROX [18] for exploratory item selection, and DIMTEST [17] for confirmatory hypothesis testing with respect to test composition.

Manifest-monotonicity Based Methods

The second observable property is manifest monotonicity [6]. It can be used to investigate assumption

4 Nonparametric Item Response Theory Models

M. To estimate the IRF for item j , $P_j(\theta)$, first a sum score on $J - 1$ items excluding item j ,

$$R_{(-j)} = \sum_{k \neq j} X_k, \quad (13)$$

is used as an estimate of θ , and then the conditional probability $P[X_j = 1 | R_{(-j)} = r]$ is calculated for all values r of $R_{(-j)}$. Given the assumptions of UD, LI, and M, the conditional probability $P[X_j = 1 | R_{(-j)}]$ must be nondecreasing in $R_{(-j)}$; this is manifest monotonicity.

Investigating assumption M. The computer program MSP5 can be used for estimating probabilities, $P[X_j = 1 | R_{(-j)}]$, plotting the discrete response functions for $R_{(-j)} = 0, \dots, J - 1$, and testing violations of manifest monotonicity for significance. The program TestGraf98 [11, 12] estimates continuous response functions using kernel smoothing, and provides many graphics. These response functions include, for example, the option response functions for each of the response options of a multiple-choice item.

Investigating assumption IIO. To investigate whether the items j and k have intersecting IRFs, the conditional probabilities $P[X_j = 1 | R_{(-j, -k)}]$ and $P[X_k = 1 | R_{(-j, -k)}]$ can be compared for each value $R_{(-j, -k)} = r$, and the sign of the difference can be compared with the sign of the difference of the sample item means, $\bar{X}_j$ and $\bar{X}_k$, for the whole group. Opposite signs for some r values indicate intersection of the IRFs and are tested against the null hypothesis that $P[X_j = 1 | R_{(-j, -k)} = r] = P[X_k = 1 | R_{(-j, -k)} = r]$ – meaning that the IRFs coincide locally – in the population. This method and other methods for investigating an IIO have been discussed and compared by [15] and [16]. MSP5 [9] can be used for investigating IIO.

Many of the methods mentioned have been generalized to polytomous items, but research in this area is still going on. Finally, we mention that methods for estimating the reliability of total score X_+ have been developed under the assumptions of UD, LI, M, and IIO, both for dichotomous and polytomous items [16].

Developments, Alternative Models

NIRT developed later than parametric IRT. It is an expanding area, both theoretically and practically.

New developments are in adaptive testing, differential item functioning, person-fit analysis, and cognitive modeling. The analysis of the dimensionality of test and questionnaire data has received much attention, using procedures implemented in the programs DETECT, HCA/CCPROX, DIMTEST, and MSP5. Latent class analysis has been used to formulate NIRT models as discrete, ordered latent class models and to define fit statistics for these models. Modern estimation methods such as **Markov Chain Monte Carlo** have been used to estimate and fit NIRT models. Many other developments are ongoing.

The theory discussed so far was developed for analyzing data generated by means of monotone IRFs, that is, data that conform to the assumption that a higher θ value corresponds with a higher expected item score, both for dichotomous and polytomous items. Some item response data reflect a choice process governed by personal preferences for some but not all items or stimuli, and assumption M is not adequate. For example, a marketing researcher may present subjects with J brands of beer, and ask them to pick any number of brands that they prefer in terms of bitterness; or a political scientist may present a sample of voters with candidates for the presidency and ask them to order them with respect to perceived trustworthiness. The data resulting from such tasks require IRT models with single-peaked IRFs. The maximum of such an IRF identifies the item location or an interval on the scale – degree of bitterness or trustworthiness – at which the maximum probability of picking that stimulus is obtained. See [10] and [5] for the theoretical foundation of NIRT models for single-peaked IRFs and methods for investigating model-data fit.

Nonparametric Regression

Nonparametric regression analysis traces the dependence of a response variable (y) on one or several predictors (x s) without specifying in advance the function that relates the response to the predictors:

$$E(y_i) = f(x_{1i}, \dots, x_{pi}) \quad (1)$$

where $E(y_i)$ is the mean of y for the i th of n observations. It is typically assumed that the conditional variance of y , $\text{Var}(y_i | x_{1i}, \dots, x_{pi})$ is a constant, and that the conditional distribution of y is normal, although these assumptions can be relaxed.

Nonparametric regression is therefore distinguished from linear regression (see **Multiple Linear Regression**), in which the function relating the mean of y to the x s is linear in the parameters,

$$E(y_i) = \alpha + \beta_1 x_{1i} + \dots + \beta_p x_{pi} \quad (2)$$

and from traditional nonlinear regression, in which the function relating the mean of y to the x s, though nonlinear in its parameters, is specified explicitly,

$$E(y_i) = f(x_{1i}, \dots, x_{pi}; \gamma_1, \dots, \gamma_k) \quad (3)$$

In traditional regression analysis, the object is to estimate the parameters of the model – the β s or γ s. In nonparametric regression, the object is to estimate the regression function directly.

There are many specific methods of nonparametric regression. Most, but not all, assume that the regression function is in some sense smooth. Several of the more prominent methods are described in this article. Moreover, just as traditional linear and nonlinear regression can be extended to **generalized linear model** and nonlinear regression models that accommodate nonnormal error distributions, the same is true of nonparametric regression. There is a large literature on nonparametric regression analysis, both in scientific journals and in texts. For more extensive introductions to the subject, see in particular, Bowman and Azzalini [1], Fox [2, 3], Hastie, Tibshirani, and Freedman [4], Hastie and Tibshirani [5], and Simonoff [6].

The simplest use of nonparametric regression is in smoothing scatterplots (see **Scatterplot Smoothers**). Here, there is a numerical response y and a single predictor x , and we seek to clarify visually

the relationship between the two variables in a scatterplot. Figure 1, for example, shows the relationship between female expectation of life at birth and GDP per capita for 154 nations of the world, as reported in 1998 by the United Nations. Two fits to the data are shown, both employing local-linear regression (described below); the solid line represents a fit to all of the data, while the broken line omits four outlying nations, labelled on the graph, which have values of female life expectancy that are unusually low given GDP per capita. It is clear that although there is a positive relationship between expectation of life and GDP, the relationship is highly nonlinear, leveling off substantially at high levels of GDP.

Three common methods of nonparametric regression are *kernel estimation* (see **Kernel Smoothing**), *local-polynomial regression* (which is a generalization of kernel estimation), and *smoothing splines*. *Nearest-neighbor* kernel estimation proceeds as follows (as illustrated for the UN data in Figure 2):

1. Let x_0 denote a focal x -value at which $f(x)$ is to be estimated; in Figure 2(a), the focal value is the 80th ordered x -value in the UN data, $x_{(80)}$. Find the m nearest x -neighbors of x_0 , where $s = m/n$ is called the *span* of the kernel smoother. In the example, the span was set to $s = 0.5$, and thus $m = 0.5 \times 154 = 77$. Let h represent the half-width of a window encompassing the m nearest neighbors of x_0 . The larger the span (and hence the value of h), the smoother the estimated regression function.
2. Define a symmetric unimodal weight function, centered on the focal observation, that goes to zero (or nearly zero) at the boundaries of the neighborhood around the focal value. The specific choice of weight function is not critical: In Figure 2(b), the tricube weight function is used:

$$w_T(x) = \begin{cases} \left[1 - \left(\frac{|x - x_0|}{h} \right)^3 \right]^3 & \text{for } \frac{|x - x_0|}{h} < 1 \\ 0 & \text{for } \frac{|x - x_0|}{h} \geq 1 \end{cases} \quad (4)$$

A Gaussian (normal) density function is another common choice.

3. Using the tricube (or other appropriate) weights, calculate the weighted average of the y -values to

Figure 1 Female expectation of life by GDP per capita, for 154 nations of the world. The solid line is for a local-linear regression with a span of 0.5, while the broken line is for a similar fit deleting the four outlying observations that are labeled on the plot

obtain the fitted value

$$\hat{y}_0 = \hat{f}(x_0) = \frac{\sum W_T(x_i)y_i}{\sum W_T(x_i)} \quad (5)$$

as illustrated in Figure 2(c). Greater weight is thus accorded to observations whose x -values are close to the focal x_0 .

4. Repeat this procedure at a range of x -values spanning the data – for example, at the ordered observations $x_{(1)}, x_{(2)}, \dots, x_{(n)}$. Connecting the fitted values, as in Figure 2(d), produces an estimate of the regression function.

Local-polynomial regression is similar to kernel estimation, but the fitted values are produced by locally weighted regression rather than by locally weighted averaging; that is, $\hat{y}_0$ is obtained in step 3 by the polynomial regression of y on x to minimize the weighted sum of squared residuals

$$\sum W_T(x_i)(y_i - a - b_1x_i - b_2x_i^2 - \dots - b_kx_i^k)^2 \quad (6)$$

Most commonly, the order of the local polynomial is taken as $k = 1$, that is, a local linear fit (as

in Figure 1). Local- polynomial regression tends to be less biased than kernel regression, for example, at the boundaries of data – as is evident in the artificial flattening of the kernel estimator at the right of Figure 2(d). More generally, the bias of the local-polynomial estimator declines and the variance increases with the order of the polynomial, but an odd-ordered local-polynomial estimator has the same asymptotic variance as the preceding even-ordered estimator: Thus, the local-linear estimator (of order 1) is preferred to the kernel estimator (of order 0), and the local-cubic (order 3) estimator to the local-quadratic (order 2).

Smoothing splines are the solution to the *penalized regression problem*: Find $\hat{f}(x)$ to minimize

$$S(h) = \sum [y_i - f(x_i)]^2 + h \int_{x(1)}^{x(n)} [f''(x)]^2 dx \quad (7)$$

Here h is a *roughness penalty*, analogous to the span in nearest-neighbor kernel or local-polynomial regression, and f'' is the second derivative of the

Figure 2 How the kernel estimator works: (a) A neighborhood including the 77 observations closest to $x_{(80)}$, corresponding to a span of 0.5. (b) The tricube weight function defined on this neighborhood; the points show the weights for the observations. (c) The weighted mean of the y -values within the neighborhood, represented as a horizontal line. (d) The nonparametric regression line connecting the fitted values at each observation. (The four outlying points are excluded from the fit)

regression function (taken as a measure of roughness). Without the roughness penalty, nonparametrically minimizing the residual sum of squares would simply interpolate the data. The mathematical basis for smoothing splines is more satisfying than for kernel or local polynomial regression, since an explicit criterion of fit is optimized, but spline and local-polynomial regressions of equivalent smoothness tend to be similar in practice.

Local regression with several predictors proceeds as follows, for example. We want the fit $\hat{y}_0 = \hat{f}(\mathbf{x}_0)$ at the focal point $\mathbf{x}_0 = (x_{10}, \dots, x_{p0})$ in the predictor space. We need the distances $D(\mathbf{x}_i, \mathbf{x}_0)$ between the observations on the predictors and the focal point. If the predictors are on the same scale (as, for example,

when they represent coordinates on a map), then measuring distance is simple; otherwise, some sort of standardization or generalized distance metric will be required. Once distances are defined, weighted polynomial fits in several predictors proceed much as in the bivariate case. Some kinds of spline estimators can also be generalized to higher dimensions.

The generalization of nonparametric regression to several predictors is therefore mathematically straightforward, but it is often problematic in practice. First, multivariate data are afflicted by the so-called *curse of dimensionality*: Multidimensional spaces grow exponentially more sparse with the number of dimensions, requiring very large samples to estimate nonparametric regression models with many

4 Nonparametric Regression

predictors. Second, although slicing the surface can be of some help, it is difficult to visualize a regression surface in more than three dimensions (that is, for more than two predictors).

Additive regression models are an alternative to unconstrained nonparametric regression with several predictors. The additive regression model is

$$E(y_i) = \alpha + f_1(x_{1i}) + \cdots + f_p(x_{pi}) \quad (8)$$

where the f_j are smooth partial-regression functions, typically estimated with smoothing splines or by local regression. This model can be extended in two directions: (1) To incorporate interactions between (or among) specific predictors; for example

$$E(y_i) = \alpha + f_1(x_{1i}) + f_{23}(x_{2i}, x_{3i}) \quad (9)$$

which is not as general as the unconstrained model $E(y_i) = \alpha + f(x_{1i}, x_{2i}, x_{3i})$. (2) To incorporate linear terms, as in the model

$$E(y_i) = \alpha + \beta_1 x_{1i} + f_2(x_{2i}) \quad (10)$$

Such *semiparametric* models are particularly useful for including dummy regressors or other contrasts derived from categorical predictors.

Returning to the UN data, an example of a simple additive regression model appears in Figures 3 and 4. Here female life expectancy is regressed on GDP per capita and the female rate of illiteracy, expressed

Figure 3 Fitted regression surface for the additive regression of female expectation of life on GDP per capita and female illiteracy. The vertical lines represent residuals

Figure 4 Partial regression functions from the additive regression of female life expectancy on GDP per capita and female illiteracy; each term is fit by a smoothing spline using the equivalent of four degrees of freedom. The “rug plot” at the bottom of each graph shows the distribution of the predictor, and the broken lines give a point-wise 95-percent confidence envelope around the fit

as a percentage. Each term in this additive model is fit as a smoothing spline, using the equivalent of four degrees of freedom. Figure 3 shows the two-dimensional fitted regression surface, while Figure 4 shows the partial-regression functions, which in effect slice the regression surface in the direction of each predictor; because the surface is additive, all slices in a particular direction are parallel, and the two-dimensional surface in three-dimensional space can be summarized by two two-dimensional graphs. The ability to summarize the regression surface with a series of two-dimensional graphs is an even greater advantage when the surface is higher-dimensional.

A central issue in nonparametric regression is the selection of smoothing parameters – such as the span in kernel and local-polynomial regression or the

roughness penalty in smoothing-spline regression (or equivalent degrees of freedom for any of these). In the examples in this article, smoothing parameters were selected by visual trial and error, balancing smoothness against detail. The analogous statistical balance is between variance and bias, and some methods (such as **cross-validation**) attempt to select smoothing parameters to minimize estimated mean-square error (i.e., the sum of squared bias and variance).

Nonrandom Samples

Many of the questions that the tools of modern statistics are enlisted to help answer are causal. To what extent does exercise cause a decrease in coronary heart disease? How much of an effect does diet have on cholesterol in the blood? How much of a child's performance in school is due to home environment? What proportion of a product's sales can be traced to a new advertisement campaign? How much of the change in national test scores can be attributed to modifications in educational policy?

Some of these questions lend themselves to the possibility of experimental study. One could randomly assign a large group of individuals to a program of exercise, command another to a more sedentary life, and then compare the coronary health of the two groups years later (see **Clinical Trials and Intervention Studies**). This is possible but impractical. Similar *gedanken* experiments could be imagined on diet, but the likelihood of actually accomplishing any long-term controlled experiment on humans is extremely small. Trying to control the home life of children borders on the impossible.

Modern epistemology [3] points out that the **randomization** associated with a true experimental design is the only surefire way to measure the effects of possible causal agents. The randomization allows us to control for any 'missing third factor' because, under its influence, any unknown factor will be evenly distributed (in the limit) in both the treatment and control conditions. Yet, as we have just illustrated, many of modern causal questions do not lend themselves easily to the kind of randomized assignment that is the hallmark of tightly controlled experiments. Instead, we must rely on observational studies – studies in which our data are not randomly drawn.

In an **observational study**, we must examine intact groups – perhaps one group of individuals who have followed a program of regular exercise and another who have not – and compare their cardiovascular health. But it is almost certain that these two groups differ on some other variable as well – perhaps diet or age or weight or

social class. These must be controlled for statistically. Without random assignment, we can never be sure we have controlled for everything, but this is the best that we can do. In fact, thanks to the ingenious efforts of many statisticians (e.g., [1, 2, 8, 9, 10, 11]) in many circumstances, there are enough tools available for us to do very well indeed.

Let us now consider three separate circumstances involving inferences from nonrandomly gathered data. In the first two, the obvious inferences are wrong, and in the third, we show an ingenious solution that allows what appears to be a correct inference. In each case, we are overly terse, but provide references for more detailed explanation.

Example 1. The most dangerous profession In 1835, the Swiss physician H. C. Lombard [5] published the results of a study on the longevity of various professions. His data were very extensive, consisting of death certificates gathered over more than a half century in Geneva. Each certificate contained the name of the deceased, his profession, and age at death. Lombard used these data to calculate the mean longevity associated with each profession. Lombard's methodology was not original with him, but, instead, was merely an extension of a study carried out by R. R. Madden, Esq. that was published two years earlier [6]. Lombard found that the average age of death for the various professions mostly ranged from the early 50s to the mid 60s. These were somewhat younger than those found by Madden, but this was expected since Lombard was dealing with ordinary people rather than the 'geniuses' in Madden's (the positive correlation between fame and longevity was well known even then). But Lombard's study yielded one surprise; the most dangerous profession – the one with the shortest longevity – was that of 'student' with an average age of death of only 20.7! Lombard recognized the reason for this anomaly, but apparently did not connect it to his other results (for more details see [12]).

Example 2. The twentieth century is a dangerous time In 1997, to revisit Lombard's methodology, Samuel Palmer and Linda Steinberg (reported in [13]) gathered 204 birth and death dates from the Princeton (NJ) Cemetery. This cemetery opened in the mid 1700s, and has people buried in it born in

2 Nonrandom Samples

Figure 1 The longevities of 204 people buried in Princeton Cemetery shown as a function of the year of their birth

the early part of that century. Those interred include Grover Cleveland, John Von Neumann, Kurt Gödel, and **John Tukey**.

When age-at-death was plotted as a function of birth year (after suitable smoothing to make the picture coherent), we see the result shown as Figure 1. The age of death stays relatively constant until 1920, when the longevity of the people in the cemetery begins to decline rapidly. The average age of death decreases from around 70 years of age in the 1900s to as low as 10 in the 1980s. It becomes obvious immediately that there must be a reason for the anomaly in the data (what we might call the 'Lombard Surprise'), but what? Was it a war or a plague that caused the rapid decline? Has a neonatal section been added to the cemetery? Was it opened to poor people only after 1920? Obviously, the reason for the decline is nonrandom sampling. People cannot be buried in the cemetery if they are not already dead. Relatively few people born in the 1980s are buried in the cemetery and, thus, no one born in the 1980s that we found in Princeton Cemetery could have been older than 17.

Examples of situations in which this anomaly arises abound. Four of these are:

1. In 100 autopsies, a significant relationship was found between age-at-death and the length of the lifeline on the palm [7]. Actually, what they discovered was that wrinkles and old age go together.
2. In 90% of all deaths resulting from barroom brawls, the victim was the one who instigated the fight. One questions the wit of the remaining 10% who did not point at the body on the floor when the police asked, 'Who started this?'
3. In March of 1991, the *New York Times* reported the results of data gathered by the American Society of Podiatry, which stated that 88% of all women wear shoes at least one size too small. Who would be most likely to participate in such a poll?
4. In testimony before a February 1992 meeting of a committee of the Hawaii State Senate, then considering a law requiring all motorcyclists to wear a helmet, one witness declared that, despite having been in several accidents during his 20 years of motorcycle riding, a helmet would not have prevented any of the injuries he received. Who was unable to testify? Why?

Example 3. Bullet holes and a model for missing data Abraham Wald, in some work he did during World War II [14], was trying to determine where to add extra armor to planes on the basis of the pattern of bullet holes in returning aircraft. His conclusion was to determine carefully where returning planes had been shot and *put extra armor every place else!*

Wald made his discovery by drawing an outline of a plane (crudely shown in Figure 2), and then putting a mark on it where a returning aircraft had been shot. Soon, the entire plane had been covered with marks *except* for a few key areas. It was at this point that he interposed a model for the missing data, the planes that did not return. He assumed that planes had been hit more or less uniformly, and, hence, those aircraft hit in the unmarked places had been unable to return, and, thus, were the areas that required more armor.

Wald's key insight was his model for the non-response. From his observation that planes hit in certain areas were still able to return to base, Wald inferred that the planes that did not return must have been hit somewhere else. Note that if he used a different model analogous to 'those lying within Princeton Cemetery have the same longevity as those without' (i.e., that the planes that returned were hit about the same as those that did not return), he would have arrived at exactly the opposite (and wrong) conclusion.

To test Wald's model requires heroic efforts. Planes that did not return must be found and the patterns of bullet holes in them must be recorded. In short, to test the validity of Wald's model for missing data requires that we sample from the unselected population – we must try to get a random sample,

Figure 2 A schematic representation of Abraham Wald's ingenious scheme to investigate where to armor aircraft

even if it is a small one. This strategy remains the basis for the only empirical solution to making inferences from nonrandom samples.

Nonresponse in surveys (*see Nonresponse in Sample Surveys*) exhibits many of the same problems seen in observational studies. Indeed, in a mathematical sense, they are formally identical. Yet, in practice, there are important distinctions that can usefully be drawn between them [4]. This essay was aimed at providing a flavor of the depth of the problems associated with making correct inferences from nonrandomly gathered data, and an illustration of the character of one solution – Abraham Wald's – which effectively models the process that generated the data in the hope of uncovering its secrets.

Nonresponse in Sample Surveys

Consider a sample survey of n units from a population containing N units. During the data collection phase of the survey, attempts are made to collect information from each of the n sampled units. Generally, for a variety of reasons, there is a subset of units from which it is not possible to collect the information. For example, if the units are patient hospital medical records, the records may be missing. If the unit is a household, and the survey uses telephone interviewing, the household respondent may rarely be at home or may be unwilling to participate in the survey. These are just two of a countless number of scenarios in which information cannot be obtained from a sampled unit (*see Missing Data*). The nonresponse from a sampled unit is considered to be one of the major threats to the validity of information obtained by the use of sample surveys [6–8].

Effects of Nonresponse

The nonresponse of sample units is responsible for a smaller sample size, and, hence, larger variances or standard errors in the resulting estimates than were planned for in the original study design. More importantly, the nonresponse results in bias that is insidious because it cannot be estimated directly from the survey data. For any variable measured in the survey, this bias is equal to the product of the expected proportion of nonrespondents in the population and the expected difference between the level of the variable among respondents and nonrespondents [9, 12]. Thus, if 30% of households in a population are potential nonrespondents, and if 40% of the potential nonrespondents are below the poverty level as opposed to 10% of the potential respondents, then the expected estimated proportion of households below the poverty level from the survey will be 10%, which is a gross underestimate of the true level which is 19% ($0.30 \times 40\% + 0.70 \times 10\%$).

Types of Response Rates and Issues in Reporting Them

Because of the potential biases due to nonresponse, it is very important that response rates be reported in

the findings of a sample survey. There are many types of response rates that can be reported, each leading to a different interpretation concerning potential biases due to nonresponse. To illustrate, let us suppose that a firm has given special training on the use of a new software package to 1000 employees and, a year later, selects a random sample of 200 for interviews on their satisfaction with the software and the training. Of the 200, they are able to successfully interview 120, which is a response rate of 60% of those given the training. However, of the 80 that were not interviewed, 50 were no longer employed at the firm; 10 refused to be interviewed; and 20 were either ill or on vacation during the period in which interviews occurred. Thus, if one considers only those available during the period of the survey, the response rate would be 120/130 (92.3%). If one considers only those still employed during the survey, the response rate would be 120/150 (80%). Each of these three response rates would lead to a different interpretation with respect to the quality of the data and with respect to interpretations concerning the findings of the survey.

Guidelines frequently cited and used by survey professionals concerning the use of different types of response rates are given in articles by the Council of American Survey Research Organizations (CASRO) [3] and the American Association for Public Opinion Research (AAPOR) [1]. The material in these articles can be downloaded from their respective websites: <http://www.casro.org/resprates.cfm> and <http://www.aapor.org>. The sampling text by Lohr also discusses the various types of response rates commonly used as well as guidelines on what constitutes an acceptable response rate [12, pp. 281–282].

Methods of Improving Response Rates

While 100% response rates are generally unattainable, there are a variety of methods commonly used to improve response rates. Most of these methods can be found in recent textbooks on sampling or survey methodology [9, 12], or in more specialized publications dealing with response issues [4, 6–8, 10, 11]. We now present a brief description of several widely used methods.

Endorsements. Response rates can be increased if the survey material contains endorsements by an

2 Nonresponse in Sample Surveys

agency or organization whose sphere of interest is strongly associated with the subject matter of the survey. This works best if the name of the endorsing organization or individual signing the endorsement letter is well known to the potential respondents. This is especially effective in surveys of business, trade, or professional establishments.

Incentives. Monetary or other gifts for participation in the survey have been shown to be effective in obtaining the participation of selected units [6]. Generally, the value of the incentive should be proportional to the extent of the burden to the unit. With the increased attention given to protection of human subjects, there is a tendency for Institutional Review Boards to frown on excessive gifts, fearing that the incentives would be a form of coercion.

Refusal Conversion Attempts. Attempts to convert initial refusals often involve the use of interviewers of a different age/gender/ethnicity than that used initially (especially in face-to-face surveys). Changes in the interviewing script with more flexibility permitted for the interviewer to *ad lib* (especially in telephone surveys), and attempts to interview at a different time from that used initially are also widely used. Although the success of refusal conversion can vary considerably depending on the subject matter and interviewing mode of the survey, success rates are generally in the 15 to 25% range.

Subsampling Nonrespondents (Double Sampling). If a sample of n units from a population containing N units results in n_1 respondents and $n_2 = n - n_1$ nonrespondents, a random subsample of n^* units is taken from the n_2 units that were nonrespondents at the first phase of sampling. Intensive attempts are made to obtain data from this sample of original nonrespondents. If k of the n^* subsampled original nonrespondents are successfully interviewed, then by weighting these units by the factor n_2/k , we can obtain estimates that partially compensate for the nonresponses. The accuracy of the estimates obtained by this method depends, to a large extent, on obtaining a high response rate from the sample of original nonrespondents. Detailed descriptions of this method are given in [9].

Advance Letters in Telephone Sampling. With the switch in emphasis from the Mitofsky–Waksberg

[13] method to list assisted methods [2] of random digit dialing (RDD) in telephone surveys, it is possible to obtain addresses for a relatively high proportion of the telephone numbers obtained by RDD. By sending advance letters to the households corresponding to these numbers informing them of the nature and importance of the survey, and requesting their support, it has been shown that the response rate can be increased [11].

Multimode Options. In many surveys, where one mode of data collection (e.g., face-to-face personal interview) has not succeeded in obtaining an interview, it is possible that offering the potential target unit an alternative mode (e.g., web or mail) will result in a response. Link et al. [10] has performed an experiment in which this technique has resulted in increased response rates.

Differential Effects on Subpopulations. Although the above methods may increase overall response rates, there may be differences among subpopulations with respect to their level of effectiveness, and this may increase the diversity among various population groups with respect to response rates. How this would effect biases in the overall survey findings has become a recent concern as suggested in the recent paper by Eyerman et al. [4].

Statistical Methods of Adjusting for Nonresponse

In spite of efforts such as those mentioned above to collect data from all units selected in the sample, there will often be some units from whom survey data have not been collected. There are several methods used to adjust for this in the subsequent statistical estimation process. The ‘classic’ method is to construct classes based on characteristics that are thought to be related to the responses to the items in the survey and that are known about the nonrespondent units (often these are ecological or demographic). If a given class has n units in the original sample, but only n^* respondent units, then the initial sampling weight is multiplied by n/n^* for every unit in the particular class. This, of course, does not consider the possibility that nonrespondents, even within the same class, might differ from respondents with respect to their levels of variables in the survey. More refined methods of

adjustment (e.g., *raking*, *propensity scores*) are now used fairly commonly and are discussed in more recent literature [5].

Nonshared Environment

Nonshared environment refers to the repeated finding that across a very wide range of individual characteristics and behaviors, children raised in the same home are often very *different* from one another [6]. Most importantly, these behavioral differences are the product of some aspect of the children's environment – and not to differences in their genes. Nonshared environmental influences may include different peer groups or friendships, differential parenting, differential experience of trauma, different work environments, and different romantic partners or spouses. The difficulty, however, has been in finding evidence of the substantial and systematic impact of any of these variables on sibling differences. Nonshared environment remains a 'hot topic' in the field of quantitative genetic research because it has been shown to be important to a wide array of behaviors across the entire life-span, and yet its *systematic* causes remain elusive [12].

How are we able to discern the extent to which nonshared environmental factors are operating on a behavior? Just as genetic influences on behaviors are inferred from comparisons of different sibling types, so can nonshared environmental outcomes be detected through similar comparisons. For example, monozygotic (MZ, or identical) twins are 100% genetically identical. This means that when members of an MZ twin pair differ, these differences cannot be due to genetic differences – they must be the result of differential effects of factors within each twin's respective *environment*. This unique opportunity to separate the effects of genes and environment on behavior has made identical twins very popular among behavioral geneticists (see **Twin Designs**).

Prior to describing the promising results of one recent study of nonshared environmental associations, we wish to point out an important distinction among such studies. While it is clear that within-family differences are substantial for most behaviors, until recently the *sources* of these differences have remained 'anonymous'. That is, quantitative genetic analyses of individual behaviors at one time point (i.e., univariate, cross-sectional analyses) can only tell us siblings are different because of factors in their environments. For example, if we find substantial differences in levels of depression *within MZ twin pairs*, nonshared environmental influence

on depression is indicated. We still do not know, however, what factors are causing, or contributing to, these behavioral differences. It is only recently that researchers have begun to assess the causes of within-family differences by examining nonshared environmental *associations* between constructs thought to be environmental (e.g., peer relations) and adjustment (e.g., depression).

In the simplest form of these bivariate analyses, MZ twin differences on an environmental factor are correlated with MZ twin differences on an adjustment factor. This correlation between MZ twin differences on two constructs allows the 'pure' nonshared environmental association for this association to be estimated. The MZ twin difference method is ideal in its relative simplicity and its stringency, since reduced sample sizes and the general tendency for MZ twins to be *more* similar rather than less similar to one another than DZ twins decrease the likelihood of finding significant associations. Yet, there have been very few quantitative genetic analyses that have used an MZ differences approach. Of those that have, there has been an almost exclusive reliance on self-reports of both the environment, often retrospective family environment, and current psychological adjustment (e.g. [1, 2]). While this does not diminish the importance of the findings, the use of within-reporter difference correlations (i.e., correlations between two measures reported by the same informant) is subject to the same criticism that applies to standard, two-variable correlations: the correlations are more likely to represent rater bias of some sort than are correlations between ratings from two different reporters (see **Rater Bias Models**).

One recent MZ difference analysis of nonshared environmental influences on the socio-emotional development of preschool children provides evidence for at least moderate, and in some cases substantial, nonshared environmental associations using parent, interviewer, and observer ratings [3]. In this study, across-rater MZ difference correlations between interviewer reports of parental harshness, for example, and parent reports of the children's problem behaviors, emotionality, and prosocial behavior were .36, .38, and -.27, respectively. Cross-rater MZ difference correlations were also significant for: (a) parental positivity and child positivity, (b) parental positivity and child problem behavior (a negative association), (c) parental negative control and child prosocial behavior (a negative association), and (d) parental

2 Nonshared Environment

harsh discipline and child responsiveness (a negative association). These findings can be interpreted as evidence that the *differential treatment* of very young siblings living in the same family by their parents *matters* – and it matters *apart from any genetically influenced traits of the child*. For example, when a parent is harsh toward one child, and less harsh to the other, the child receiving the harsh discipline is more likely to have behavior problems, be more emotionally labile, and be less prosocial than their sibling.

One alternative explanation of the findings reported by Deater–Deckard and colleagues [3] is that differences in the children’s behaviors elicit differences in parenting, or that the relationship is reciprocal. Unfortunately, it is not possible to directly test for this using cross-sectional data. A similar set of preliminary analyses of parent–child data from an adult twin sample, the Twin Moms project [7], found several substantial cross-rater MZ difference correlations between the differential parenting patterns of adult twin women and characteristics of their adolescent children [10]. While it is also not possible to confirm directionality in this cross-sectional sample, such findings in an *adult-based* sample imply that differences in the children are contributing to differences in (or nonshared environmental variation in) the parenting behavior of the mothers, since the mothers’ genes and environment are the focus of assessment.

Regardless of the direction of effect, the associations reported by Deater–Deckard and colleagues [3] are remarkable for at least two reasons. First, within-family differences have been shown to increase over time – and to be less easily detected in early childhood, when parents are more likely to treat their children similarly [5, 9]. Finding associations between differential parenting, a family environment variable, and childhood behaviors using a sample of three and a half-year-old children is notable, and has implications for clinical intervention efforts directed toward promoting more ‘equitable’ parenting of siblings. Second, the fact that these associations exist across three different rater ‘perspectives’ lends credence to the validity of the associations – they cannot be attributed entirely to the bias of a single reporter. Third, unlike univariate analyses of nonshared environment, analyses of multivariable associations minimize the amount of measurement error in the estimate of nonshared environment.

In light of this apparent success, one may ask, why all the excitement over nonshared environment? Again, the issue is an inability to isolate *systematic* sources of within-family differences in behavior, which are so prevalent. In other words – where single studies have succeeded in specifying sources of sibling differences, there has been a general failure to replicate these findings across samples. A recent **meta-analysis** of the effect produced by candidate sources of nonshared environment on behavior found the average effect size of studies *using genetically informed designs* to be roughly 2% [12]. Revelations of this kind have stirred discussion about the definition of nonshared environment itself [4, 8]. So far, however, the study of nonshared environmental associations has been limited almost exclusively to analyses of children and adolescents.

As adult siblings often go their separate ways – rent their own place, get a job, get married, and so on – it comes as no surprise that nonshared environmental variation may increase with age [5]. It seems a viable possibility, then, that primary sources of nonshared environmental influence on behavior are to be found in adulthood. Indeed, results from the Twin Moms project [7] indicate that a portion of the nonshared environmental variation in women’s marital satisfaction covaries with differences in the women’s spousal characteristics, current family environment, and stressful life events [11]. In other words, the extent to which women are satisfied or dissatisfied with their marriages has been found to vary as a function of spouse characteristics, family climate, and stressors. Importantly, these relationships exist *independently of any genetic influence* that may be operating on her feelings about her marriage. These findings confirm the potential to isolate nonshared environmental relationships among adult behaviors and relationships, and suggest an important area of exploration for future behavioral genetic work.

Finally, studies of nonshared environmental associations are important because they provide information that complements our understanding of genetic influences on behavior and relationships. Our success in quantifying the relative impact of genetic *and* environmental factors (and their mutual interplay) on human behavior has implications for therapeutic intervention. For example, the purpose of many types of therapy is to produce changes in individuals’ social environments. How much more effective these therapies may be when based on knowledge that

a particular psychosocial intervention has the potential to alter the mechanisms of genetic expression for a particular trait. For instance, intervention research has demonstrated the potential for altering behavioral responses of mothers toward their infants with difficult temperaments [13]. The intent is not only to change mothers' behaviors or thought processes, but to eliminate the *evocative association* between the infants' genetically influenced, irritable behaviors and their mothers' corresponding expressions of hostility. By identifying specific sources of nonshared environmental influences, we will be better able to focus our attention on the environmental factors that matter in eliciting behavior, as in the intervention study cited above, or that are prime candidates for examination in studies looking for **genotype x environment interaction**.

Normal Scores and Expected Order Statistics

The use of normal scores as a replacement for ranks has been advocated as a way of increasing **power** in rank-sum tests (see **Power Analysis for Categorical Methods**). The rationale is that power is compromised by the presence of tied sums in the permutation distribution (see **Permutation Based Inference**) of rank-based test statistics, for example, $1 + 6 = 2 + 5 = 3 + 4 = 7$. The likelihood of such tied sums is reduced when the ranks (integers) are replaced by scores drawn from a continuous distribution.

There are three normal score transformations in the nonparametric inference literature. For each, the raw scores are first transformed to ranks.

van der Waerden scores [7] are the best known of the normal score transformations. The ranks are replaced with quantiles of the standard normal random variable. In particular, the k th of n ranked score is transformed to the $q(k) = [k/(n+1)]$ quantile of the $N(0, 1)$ random variable. For example, for $k = 3$, $n = 10$, $q(k) = 3/11$. The corresponding van der Waerden score is that z score below which fall $3/11$ of the distribution of the standard normal. The van der Waerden scores can be obtained, of course, from tables of the standard normal. Most statistics packages, however, have normal distribution functions. For example, in the statistical language **R** (<http://www.R-project.org>) the *qnorm* function returns normal quantiles:

We can get the set of n van der Waerden scores this way:

```
> n <- 8
> qnorm((1 : n)/(n + 1))
[1] -1.22064035 -0.76470967
-0.43072730 -0.13971030 0.13971030
0.43072730
[7] 0.76470967 1.22064035
```

Expected normal order statistics were proposed by Fisher and Yates [3]. The k th smallest raw score among n is replaced by the expectation of the k th smallest score in a random sample of n observations from the standard normal distribution. Special

tables [3] or [6] often are used for the transformation but the function *normOrder* in the **R** package *SuppDists* makes the transformation somewhat more accessible.

```
> normOrder(8)
[1] -1.42363084 -0.85222503
-0.47281401 -0.15255065 0.15255065
0.47281401
[7] 0.85222503 1.42363084
```

Random normal scores can be used to extend further the support for the permutation distribution. Both van der Waerden and expected normal order statistics are symmetric about the expected value of the normal random variable. Thus, there are a number of equivalent sums involving pairs of the normal scores. By using a set of ordered randomly chosen normal scores to code the ranks, these sum equivalencies are eliminated. The rationale for this approach is further developed in [1]. In **R**, the function *rnorm* returns sampled normal scores. Thus, the command

```
> sort(rnorm(8))
[1] -1.287122544 -1.026961817
-0.149881236 -0.052743551 0.373083915
[6] 0.408619154 1.254177021 1.736467480
```

provides such a sorted set of random normal observations. A characteristic of this approach, of course, is that a second call to the function will produce a different set of random normal scores:

```
> sort(rnorm(8))
[1] -2.00484017 -0.88854417
-0.82976365 -0.75127395 -0.61653373
-0.50975136
[7] -0.14575532 0.57991888
```

An analysis that is carried out using the first set of scores will differ, perhaps substantially, from an analysis that is carried out using the second set. Is this a drawback? Perhaps, though it reminds us that whenever we replace the original observations, with ranks or with other scores, the outcome of our subsequent analysis will be dependent on our choice of recoding.

Example

The dependence of the analytic outcome on the coding of scores is illustrated by an example adopted from Loftus, G. R. & Loftus, E. F. (1988) *Essence of statistics*. New York: Knopf. Eight student volunteers watched a filmed simulated automobile accident. Then, the students read what they were told was a newspaper account of the accident, an account that contained misinformation about the accident. Four randomly selected students were told that the article was taken from the *New York Daily News*, the other four that it appeared in the *New York Times*. Finally, students were tested on their memory for the details of the accident. The substantive (alternative) hypothesis is that recall of the accident would be more influenced by the *Times* account than by one attributed to the *Daily News*. In consequence, the *Times* group was expected to make greater errors of recall than would the *Daily News* students. The reported number of errors were (4, 8, 10, 5) for the *Daily News* group and (9, 13, 15, 7) for the *Times* group.

Permutation tests (see **Permutation Based Inference**) are used here to test the null hypothesis of equal errors for the two attributions against the alternative. The test statistic used in each instance is the sum of the error score codes for the *Times* students. The P value for each test is the proportion of the $8!/(4!4!) = 70$ permutations of the error score codes for which the *Times* sum is as large or larger than for the observed randomization of cases. Table 1 shows the variability in the P value over the different codings of the error scores.

Table 1 P values for different codings of responses

Error score coding	P value
Raw scores	$5/70 = 0.07143$
Ranks	$7/70 = 0.10000$
van der Waerden scores	$6/70 = 0.08571$
Expected normal order statistics	$8/70 = 0.11430$
Random normals, set 1	$5/70 = 0.07143$
Random normals, set 2	$7/70 = 0.10000$

The raw scores permutation test is the **Pitman test** and the rank-based permutation test is the **Wilcoxon Mann-Whitney test**. The normal codings of the ranked errors for the remaining four permutation tests are the ones reported earlier. All six permutation tests were carried out using the **R** function `perm.test` in the `exactRankTests` package.

Summary

The indeterminacy of the random normal scores and the relative difficulty of determining expected normal order statistics have made van der Waerden scores the most common choice for normal scores. Asymptotic inference techniques for normal scores tests are outlined in [2]. More appropriate to small sample studies, however, are inferences based on the exact permutation distribution of the test statistic or a Monte Carlo approximation to that distribution. Such normal scores test are available, for example, in StatXact (<http://www.cytel.com>) and the general ideas are described in [4] and [5].

Nuisance Variables

Nuisance variables are associated with variation in an outcome (dependent variable) that is extraneous to the effects of independent variables that are of primary interest to the researcher. In experimental comparisons among randomly formed treatment groups, the impact of nuisance variables is to increase experimental error and, thereby, decrease the likelihood that true differences among groups will be detected. Procedures that control nuisance variables, and thereby reduce experimental error, can be expected to increase the **power** for detecting group differences. In addition to randomization, there are three fundamental approaches to controlling for the effects of nuisance variables. First, cases may be selected to be similar for one or more nuisance variables (e.g., only 6-year-old girls with no diagnosed learning difficulties are included in a study). Second, statistical adjustments may be made using stratification (e.g., cases are stratified by sex and grade in school). Note that the most complete **stratification** occurs when cases are matched one-to-one prior to application of experimental treatments. Stratification, or **matching**, on more than a small number of nuisance variables is often not practical. Third, statistical adjustment can be made using regression procedures (e.g., academic ability is used as a covariate in **analysis of covariance**, ANCOVA). In the social sciences, **randomization** is considered a *sine qua non* for experimental research. Thus, even when selection, stratification, and/or covariance adjustment is used, randomization is still necessary for controlling unrecognized nuisance variables.

Although randomization to experimental treatment groups guarantees their equivalence *in expectation*, the techniques of selection, stratification, and/or covariance adjustment are still desirable in order to increase statistical power. For example, if cases are stratified by grade level in school, then differences among grades and the interaction between grades and experimental treatments are no longer confounded with experimental error. In practice, substantial increases in statistical power can be achieved by controlling nuisance variances. Similarly, when

ANCOVA is used, the variance due to experimental error is reduced in proportion to the squared correlation between the dependent variable and the covariate. Thus, the greatest benefit from statistical adjustment occurs when the nuisance variables are strongly related to the dependent variable. In effect, controlling nuisance variables can reduce the sample size required to achieve a desired level of statistical power when making experimental comparisons.

While controlling nuisance variables may enhance statistical power in nonexperimental studies, the major impetus for this control is that, in the absence of randomization, comparison groups cannot be assumed to be equivalent in expectation. Thus, in nonexperimental studies, the techniques of matching, stratification, and/or ANCOVA are utilized in an effort to control preexisting differences among comparison groups. Of course, complete control of nuisance variables is not possible without randomization. Thus, nonexperimental studies are always subject to threats to **internal validity** from unrecognized nuisance variables. For example, in a **case-control study**, controls may be selected to be similar to the cases and matching, stratification, and/or ANCOVA may be used, but there is no assurance that all relevant nuisance variables have been taken into account. Uncontrolled nuisance variables may be confounded with the effects of treatment in such a way that comparisons are biased.

For studies involving the prediction of an outcome rather than comparisons among groups (e.g., **multiple regression** and **logistic regression** analysis), the same general concepts that apply to nonexperimental studies are relevant. In regression analysis, the independent contribution of a specific predictor, say *X*, can be assessed in the context of other predictors in the model. These other predictors may include dummy-coded stratification variables and/or variables acting as covariates (see **Dummy Variables**). Then, a significance test for the regression coefficient corresponding to *X* will be adjusted for these other predictors. However, as in the case of any nonexperimental study, this assessment may be biased owing to unrecognized nuisance variables.

Number of Clusters

An issue that frequently occurs in cluster analysis is how many clusters are present, or which partition is ‘best’ (see **Cluster Analysis: Overview**)? This article discusses stopping rules that have been proposed for determining the best number of clusters, and concludes with a pragmatic approach to the problem for social science investigations.

In **hierarchical classification** the investigator is presented with a complete range of clusters, from one (the entire data set), to n , the number of cases (where each cluster has one member). In the early stages of agglomerative clustering, each cluster comprises either a single case or a small homogeneous grouping of cases that are very similar. At the later stages, clusters are combined to form larger – more heterogeneous – groups of cases, and at the penultimate stage there are only two clusters that constitute, in terms of the clustering method, the best two groups. Clusters formed at the later stages therefore exhibit increasingly less homogeneity or greater heterogeneity. Divisive clustering methods work in the opposite direction – at the first stage dividing the sample into the two most homogeneous subgroups, then further subdividing the subgroups, and so on until a stopping rule can be applied or each cluster contains a single case and cannot be further subdivided. The issue of which partition is ‘best’ therefore resolves in some sense as to how much heterogeneity can be tolerated in the latest cluster formed by agglomeration or split by division.

Numerous procedures have been proposed for determining the best number of clusters in a data set. In a review of 30 such rules, Milligan and Cooper [8] present a Monte Carlo evaluation of the performance of the rules when applied to the analysis of artificial data sets containing 2, 3, 4, or 5 distinct clusters by four hierarchical clustering methods. The procedures described below were found by Milligan and Cooper to outperform the others covered in their review.

Mojena [9] approached the question of when to stop a hierarchical agglomerative process by evaluating the distribution of clustering criterion values that form the clusters at each level. These values normally constitute a series that is increasing or decreasing with each fusion. The approach is to search for an unusually large jump in an increasing series, corresponding to a disproportionate loss of homogeneity

caused by the forced fusion of two disparate clusters, despite their being the most similar of all possible fusion choices.

For example, Ward’s method obtains a series of monotonically increasing fusion values $\alpha = \{\alpha_1, \dots, \alpha_{n-1}\}$ each of which is the smallest increase in the total within-cluster error sum of squares resulting from the fusion of two clusters. Such a series is shown in Table 1. It is argued that the ‘best’ partition is the one that precedes a significant jump in α , implying that the union of two clusters results in a large loss of homogeneity and should not therefore be combined. From visual inspection of Table 1 the four-cluster partition is a likely candidate for the best partition, because the increase in the error sums of squares, E , resulting from the next fusion to form 3 clusters (4.74) is more than three times the corresponding value (1.5) at which 4 clusters were formed. There is, therefore, a large loss of homogeneity at 3 clusters.

Mojena’s Upper Tail Rule

This rule is proposed by Mojena [9]. It looks for the first value α_{j+1} that lies in the upper tail of the distribution of fusion values α , selecting the partition corresponding to the first stage j satisfying:

$$\alpha_{j+1} > \mu_\alpha + c\sigma_\alpha \quad (1)$$

where μ_α is the mean and σ_α the standard deviation of the distribution of fusion values $\alpha = \{\alpha_1, \dots, \alpha_{n-1}\}$, and c is a chosen constant, sometimes referred to as the ‘critical score’. The rule states that $n - j$ clusters are best for the first α_{j+1} that satisfies the rule. If no value for α_{j+1} satisfies the rule then one cluster is best. When α_{j+1} satisfies the rule, this means that α_{j+1} exceeds the mean μ_α of α by at least c standard deviations σ_α . It is the first big jump in α , suggesting that partition j is reasonably homogeneous whereas partition $j + 1$ is not. Partition j is therefore selected as the first best partition.

Using Ward’s method, Mojena and Wishart [10] found values of $c \leq 2.5$ performed best, whereas Milligan and Cooper [8] suggest $c = 1.25$. The reason for the discrepancy between these findings is not clear, but it may lie in the choice of proximity measure: for Ward’s method it is necessary to use a proximity matrix of *squared* Euclidean distances, whereas Milligan and Cooper computed Euclidean

2 Number of Clusters

Table 1 Fusion values in the last 10 stages of hierarchical clustering by Ward’s method. Each value is the increase in error sum of squares, E , resulting from the next fusion, thus 28.821 is the increase in E caused by joining the last 2 clusters

Number of clusters	10	9	8	7	6	5	4	3	2
Fusion values α	0.457	0.457	0.903	1.172	1.228	1.500	4.740	7.303	28.821

distances. Having evaluated a range of values of c for different artificial data sets, Milligan and Cooper concluded that the best critical score c also varied with the numbers of clusters. As the number of clusters is not known *a priori*, this finding is not generally useful.

The series in Table 1 has a mean of 2 and standard deviation of 5.96, so rule (1) checks for the first fusion value that exceeds 9.45 for a critical score of $c = 1.25$, or higher values for higher critical score c . This is not very helpful, as the only partition for which α_{j+1} exceeds 9.45 is at 2 clusters. An alternative approach is to look for the first fusion value that represents a significant departure from the mean μ_α of α , using the t test statistic:

$$\frac{\alpha_{j+1} - \mu_\alpha}{\sigma_\alpha / \sqrt{n - 1}} \quad (2)$$

which has a t distribution with $n - 2$ degrees of freedom under normality. The first partition for which (2) is significant at the 5% probability level indicates a large loss of homogeneity, and hence the previous partition j is taken as best. This has the advantages that the test takes into account the length of the α series, which determines the degrees of freedom, and eliminates the need to specify a value for the critical score c . It is implemented by Wishart [11] in his ‘Best Cut’ Clustan procedure. For the data in Table 1, which were drawn from a fusion sequence of 24 values on 25 entities, the t statistics that are significant at the 5% level with 23 degrees of freedom are 22.05, 4.36, and 2.25 at the 2, 3, and 4 cluster partitions, respectively. The t test therefore confirms the earlier intuitive conclusion for Table 1 that 4 clusters is the best level of disaggregation for these data.

It should be noted that Mojena’s upper tail rule is only defined for a hierarchical classification: it cannot be used to compare two partitions obtained by optimization because it requires a series of fusion values. Mojena [9] also evaluated a moving average quality control rule, and Mojena and Wishart [10] evaluated a double exponential smoothing rule. However, both

of these performed poorly in tests although the latter rule proved to be most accurate in predicting the next value in the α series at each stage. They concluded that the upper tail rule performed best using Ward’s method with artificial data sets.

Caliński and Harabasz’ Variance Ratio

Caliński and Harabasz [4] propose a variance ratio test statistic:
